ON THE

THEORY AND PRACTICE OF MEDICINE;

Delivered at the London University,

By Dr. Elliotson.

CUTANEOUS DISEASES.

Lecture I.—Part II.

I have spoken, gentlemen, of those diseases which may affect various parts of the body—inflammation and different structural diseases—and termed them *general* diseases. I have spoken, likewise, of certain diseases which appear to pervade nearly or entirely the whole of the body, and may be called *universal* diseases. I now come to the affections of particular parts; and I said that I should proceed from the head to the foot, *a capite ad calcem*, that being as good an arrangement as any, and much more serviceable than at least an alphabetical arrangement, as diseases are thus considered together which are situated in contiguous parts and thus must have many symptoms in common. Before we begin with the head, it will be better to consider those which affect the surface; and after we have gone over the surface, we can proceed into the interior.

Superiority of Rayer's Work to Willan's and Bateman's.—Now the diseases of the surface of the body are commonly called cutaneous diseases; but they are far more numerous than you would imagine them to be from the works of Dr. Willan and his pupil Dr. Bateman, which may be considered as the same: for the labour and honour was Willan's, and Dr. Bateman added little to what he learnt from his master, who was profoundly read in cutaneous diseases, and had laboriously observed them, though, with vulgar readers, Dr. Bateman's reputation is as great as Willan's; just as smatterers in phrenology speak of Gall and Spurzheim as equal, though the originality and glory is all Gall's, and his pupil, Dr. Spurzheim, learnt the science from him, worked under Gall, as his assistant, and has merely added to and improved upon Gall—if he has added and improved, which I will not deny—and stands at a humble distance from Gall. The best work on cutaneous diseases I conceive to be that of a French writer, Rayer. He treats of all the diseases of the skin and its appendages, thus taking a more enlarged view than Willan; and he treats of a much more considerable number of affections of the skin itself. When I say that Rayer's is altogether a much better book than Willan's, I do not at all wish to depreciate the latter, for a great part of the merit of Rayer's is ascribable to Willan: as far as Willan went, Rayer is under great obligations to him. Willan preceded Rayer, and the arrangements of the latter in reference to the subjects treated of by the former, are grounded altogether on his publication. Rayer's is the best book, on account of its arrangement, the greater number of diseases of which it speaks, and the fuller and more scientific account of the nature, causes, and treatment of the diseases. Whoever would translate Rayer, omitting his cases, so as to lessen the unnecessary size of the work, would find he had entered upon a speculation so successful, that Bateman's superficial work, synopsis only as it is, would be superseded.

General Division of Rayer.—Rayer divides the diseases of the surface of the body, first, into diseases of the skin itself; secondly, into diseases of the appendages of the skin—such as the nails, and the cutis which furnishes the nails—and in which latter diseases are to be found whitlow, and morbid conformations and structure of the nails; and the hair and sebaceous follicles, under the diseases of which he treats of plica polonica, baldness, greyness, &c. Then, thirdly, he

speaks of foreign bodies which sometimes beset the skin, as others do the intestines, and these are divided into inanimate and animate—*inanimate*, such as the stuff on the scalp of new-born infants—*animate*, which I need not say include fleas, bugs, and lice of all kinds, together with certain other animals of which we shall speak; and fourthly, those affections which commence in other parts of the body, and afterwards implicate and disfigure the skin—such as the disease called elephantiasis, in which the skin really becomes implicated only secondarily. You will observe that this is a fine comprehensive view of the diseases of the surface of the body.

Rayer's Division of Diseases of the Skin itself.—Then, when we consider diseases of the skin itself, truly cutaneous diseases, they are arranged by Rayer into six, and this is also a most excellent division. First, all those diseases of the skin which are inflammatory; secondly, those which are mere congestions, and cutaneous and subcutaneous hæmorrhages; thirdly, those which are nervous affections of the skin, such as morbid or deficient sensibility of it; fourthly, changes of colour in the skin, which are not at all dependent upon congestion; fifthly, morbid secretions of the skin; sixthly, diseases of the structure of the skin. This is a very useful view of diseases of the skin itself. They are arranged by Willan without any reference to their real nature. Willan's work (and Bateman's) is rather one of natural history than pathology. His delight and excellence was in the description of appearances. Rayer's work is excellent for deeper matters. This is the natural progress of knowledge. First, perfection is attained in distinguishing the outward appearances of objects and phenomena; and this accomplished, their nature and causes come next to be investigated. Willan accomplished much, though greatly indebted to foreign predecessors; but his labours were only a stepping-stone to what then became important. Again, I entreat you not to think I wish to depreciate his work; but we must not rest contented with progress no greater than he was able to make in the science and treatment of cutaneous diseases.

It is of the greatest importance always to consider whether cutaneous, like other diseases, are inflammatory or not, and we therefore group all those that are inflammatory together; then all those are naturally grouped that depend upon congestion, such as ecchymoses, cutaneous tumors and subcutaneous bloody tumors, sometimes called nævi materni; thirdly, those which are seated in the nerves of the part; fourthly, changes of mere colour; fifthly, morbid secretions; and sixthly, malformations, and structural changes of the skin. In this way we shall bring before us all the diseases of the skin itself.

Cutaneous Disease frequently conjoined with internal affection.—Now it is very important that we should recollect that, although these are all called diseases of the surface of the body, many of them are affections of a much deeper nature—that the affection is frequently connected with, or dependent upon, a general diseased state of the system. Frequently the mucous membranes are affected as much as the skin; for example, the conjunctiva of the eye, the Schneiderian membrane of the nose, and the mucous membranes of the mouth, throat, and of the whole of the air and alimentary passages. All these parts are liable to be affected in some diseases of the skin. I need not tell you that in measles, which is called a disease of the skin, we have frequently inflammation of the various mucous membranes which I have just named. So in the disease which is called purpura, and which is considered a disease of the skin, because there are purple spots on that organ, (I formerly mentioned that this was as much an inflammatory disease as one of congestion, and it may be entirely inflammatory) we have often the same appearances within as upon the surface. You will see the intestines, the lungs, and the liver, beset with black patches, and even parts within the head; so that in this disease blood has been effused in such a quantity that apoplexy has occurred. Although these diseases should particularly affect the skin, yet in many of them, before the affection of the skin appears, there is some internal derangement, which occasionally ceases when the external affection appears, but which sometimes continues throughout. In many there is an internal derangement at a certain time during an affection of the skin. In many of these cutaneous affections, the whole system appears more or less in an inflammatory state; and in others the whole system is in a state of extreme debility—complete exhaustion. Although, therefore, these are called diseases of the skin, from their being particularly prominent in the skin, producing very prominent symptoms there, yet it is to be remembered that many of them are of a more deep and extensive nature. Many, of course, are really local, such as changes of the colour of the skin, called *pityriasis versicolor*, where a person has a yellow appearance of the skin, a thing very common on the necks of young women; and diseases of the appendages of the skin, such as diseases of the nails, various affections of the hair and sebaceous glands. These are pure diseases of the integuments of the body, but many affections, called cutaneous diseases, are only so in one point of view.

Rayer's Arrangement of Inflammatory Affections of the Skin.—Now the inflammatory diseases of the skin are spoken of by Rayer under various classes, accordingly as there is minute or extensive inflammation—according as the inflammation produces a secretion of water or of pus—according as the inflammation is attended by scales, or produces a tubercular appearance. The inflammatory diseases of Rayer are arranged much in the same way that Willan arranges all his diseases of the skin.

Willan's general arrangement.—Willan arranges cutaneous diseases accordingly as there are mere pimples without any contents—*papulæ*. Secondly, accordingly as they are scaly—*squamæ*. Thirdly, accordingly as there are diffused patches of redness—*exanthemata*. Fourthly, as there are collections of water—*bullæ*. Fifthly, as there is a secretion of pus—*pustulæ*. Sixthly, as there are little vesicles—*vesiculæ*. Seventhly, those in which there are tubercular appearances on the skin—*tubercula*. And, eighthly, those in which there are stains—*maculæ*. Now several sets of diseases thus arranged by Willan, come, in the arrangement of Rayer, together, under the one head of inflammatory diseases.

You therefore see, in the first instance, that the diseases of the integuments of the body may be considered accordingly as they are diseases of the skin itself, or of the appendages of the skin—as there are foreign bodies upon the skin, which cases are still allowed to be called diseases of the skin—as the disease begins in other parts, and implicates the skin. And then the diseases of the skin itself may be subdivided in the way I have already stated, as they are inflammatory, congestive, nervous, changes of colour, morbid secretion, and structural change.

The inflammatory diseases of the skin are arranged by Rayer, first, as they occur in patches of inflammation—*exanthemata*; then, as they produce collections of water—*bullæ*; then, as there are minute collections of water—*vesiculæ*; then, as there is suppuration—*pustulæ*; or still larger suppuration—*furunculi*; then, as there are mere specks of inflammation—*papulæ*; then, as there are tubercular appearances,—*tubercula*; then, as there are scales produced—*squamæ*; and then, as there is inflammation in lines—*linear inflammation*; then, as there exists a disposition to gangrene—*gangrænosi*; as plague, malignant pustule, glanders; and then he makes a class called multiform, in which diseases have no fixed appearance, such as syphilis.

It appears to me that the most simple way of considering these *inflammatory* diseases is to consider them first when the inflammation is in the most minute extent—simple inflammation not larger than the point of a pin, papulæ; then we shall come to a more extensive inflammation, exanthemata; then to one which produces a little collection of water, vesiculæ; then to a large collection of water, bullæ; then, where pus is secreted, pustulæ; then, where pus is secreted in larger quantity, furuneuli, or boils; then to where the inflammation proceeds to gangrene; then where there is organic disease, first of the slightest kind—only of the cutis, as in the scaly diseases—then of a more deep kind, as in the tubercula: and so we shall go on in a more natural way than Rayer has adopted.

PAPULÆ.

We will now enter upon the consideration of inflammatory diseases of the skin itself, and, in the first place, speak of those inflammatory affections of the skin which produce no secretion whatever—no pus, no water—but consist simply in inflammation, and that of the most limited extent, producing a little speck of inflammation;—of course there may be a number of these little spots. When inflammation of the skin appears in minute spots, these are called *papulæ*; the English of which is, strictly speaking, *pimples*. The word pimple is commonly used to signify any little elevation or inflammation of the skin, whether there are no contents or whether there is water or pus; but in proper language, and to be very correct, by a *pimple* is meant a minute inflammation of the skin, causing a very small accuminated elevation of the cuticle, without any contents whatever. Dr. Willan's definition of a papula, or a true pimple, is, "a very small accuminated elevation of the cuticle," (I should suppose of the cutis and the cuticle together,) "with an inflamed base; not containing fluid nor tending to suppuration, but for the most part terminating in scurf." The duration is uncertain, but it has a tendency in general to terminate in scurf. If such a slight inflammation be attended by watery contents, it is called a *vesicle*; but if the contents be pus, we call it a *pustule*; so that with respect to the most minute inflammation of the skin, we may have a papula, a vesicle, or a pustule—mere inflammation; inflammation with water; inflammation with pus.

When this minute inflammation (papula) has no contents, it is then that it usually terminates in scurf; scurf being a very minute exfoliation of the cuticle, which will take place not only with evident inflammation, but sometimes with so exceedingly slight a degree of inflammation that we can hardly call it more than a little irritation. A new cuticle is found underneath the exfoliation; there is no rawness produced, but under the minute portion of cuticle which comes off we see a fresh cuticle; no moisture at all—the parts still perfectly dry.

These papulæ are considered, by Dr. Willan, as inflammations of the papillæ of the skin, which he considers to be enlarged, elevated, and indurated, and more or less of a red colour; but I should think, if it be the papillæ which are inflamed, we should be justified in saying, as I have said, that there is something more than elevation of the cuticle. If the papillæ be inflamed, of course we must consider the disease as situated in the cutis, the cuticle being elevated above the skin itself. The inflamed base cannot be in the cuticle; that is out of the question, and therefore it must be situated in the cutis.

Where these papulæ occur there is an uneasiness experienced, which may be called pain; but it is pain of an itching character—a painful itching, we might say.

Inflammation of this description may end in resolution, without any formation of scurf; or it may terminate in a more extensive separation of the cuticle, which is called *desquamation*—a separation of the skin in scales; for the most part, however, the cuticle is separated in such minute portions that it is only a fine dust—a *scurf* which comes off. If this inflammation be increased by the person rubbing or scratching, or by heat improperly applied, you may carry on the inflammation to the formation of water, so that you convert the papula into a vesicle. Again, if you add still more irritation, you may cause it to produce pus; you may easily convert it to a pustule. If the individual scratch himself still more, and great irritation be excited, instead of mere pustules you may have boils—pretty large collections of pus—but all this is not the tendency of the disease itself. These papulæ, which consist of mere spots of inflammation, are not contagious.

Dr. Willan makes three kinds of papulæ, but I think it would be as well to say that there are but two. These are the strophulus, or red gum, of children, the lichen of adults, and the disease called prurigo. I cannot but believe that strophulus and lichen are purely the same disease; and I think it would be a lucky thing if the name of lichen were given to both, or both names were dropped and one term substituted for them. The disease called prurigo is characterized by great itching, and is often mistaken for itch. Neither lichen nor prurigo have any particular name in English. None of these are contagious.

Strophulus.—I shall first speak of the disease called "strophulus." This is peculiar to infants, and is called by the common people *red gum* or *red gown*; it is supposed that gum is a corruption of gown; and in some old Dictionaries it is still written *redde gowne*. It is also occasionally called, by the common people, the *tooth eruption*. It is a very unimportant disease; the least irritation will cause it, whether in the gums, abdomen, &c., and with a very little attention it goes away; in fact, it need never create any alarm. It is divided by the common people into red and white; several parts of the body are affected in succession; it does not come out at once. It chiefly affects the face and extremities, and is sometimes intermittent, not periodical, but it comes and goes.

Species.—Now you will find it divided by authors into a number of tiresome varieties, which only serve to burden the memory, and are soon forgotten when you come to practise. The great point which I would urge upon you at present is, to recollect the characters of diseases in general; and as to the particular varieties, learn them afterwards, as different cases present themselves to your notice, and then do not trouble yourself so much about the names of these varieties, as about remembering the fact that there are some varieties in the appearances of the affections; and still more, what is not enough dwelt upon by subdividers, some varieties in the condition of the system and of the part affected in these diseases. It is impossible to recollect all the minute divisions of these different diseases without seeing patients, and then it is impossible to learn them all at once. It is a work of time, and there can be no doubt but that it would be quite as well if many of them were not so subdivided by authors. You will find this particular affection divided into S. intertinctus, S. albidus, S. confertus, S. volaticus, S. candidus, some of which names I shall forget as soon as I have given the lecture.

It is right, however, that you should know, that the disease which you see in babes, and which is called by old women *red gum*, is called by Dr. Willan *strophulus*.

If you give the child a dose or two of gentle physic, for the most part the affection goes away; there is no difficulty whatever in treating it. If you be aware that it appears under different varieties, you will not be surprised when you see two or three cases with a little variety; but as to its making any essential difference in the disease, or in the treatment, that is out of the question.

You will find most of these cutaneous affections represented extremely well by Drs. Willan and Bateman. Those of which I have just spoken will be found in plates 1, 2, and 3*.

If the papulæ be of a vivid red colour, but are intermixed with red dots or specks called *stigmeta*, it is then called *S. intertinctus*; Willan defines a *stigma* to be a minute, bright red speck, *without* elevation; if the

* The learned professor having principally employed the 4to. plates of these authors for the purpose of illustrating the appearance of cutaneous diseases, we shall in the subsequent lectures merely refer to their numbers, in order to avoid the repetition of their names.

papulæ consist of whitish specks, it is called *S. albidus*—that is to say, white gum, and this is often intermixed with the other; if the papulæ be all united together in the way you observe in plate 3, fig. 1, it is called *S. confertus*, and by the common people *rank* red gum, or tooth rash; it is hardly worth while to give particular names to these little variations of the disease; you will see different varieties in different parts of the same child. If the papulæ of strophulus have no inflammation at their base, (which you see is a contradiction, because a papula, according to Dr. Willan's definition, is an acuminated elevation of the cuticle, *with an inflamed base*)—if there be no inflammation at their base, and if they be of large size, they are called absolutely white, *S. candidus*. This variety usually succeeds acute diseases of children a year old. If they come, and after continuing produce a scurf and then disappear, another crop coming on, it is then called *S. volaticus*, coming and going, continuing but for a short time; the patches are circular, turn brown in a few days, and the whole series ends in a few weeks. The important point, however, will be not to recollect the names of these little particulars, (as I am sure it must be difficult to remember the differences which occasion the diseases now to be called *candidus*, and now *albidus*,) but to remember what I am about to say with regard to the general character of the disease.

This disease is sometimes pretty severe—and a great many papulæ are crowded together, and then the variety is called *S. confertus*; the papulæ are extensive, crowded, smaller, and less vivid. This form will occur in children from seven to eight months old; the patches may be hard, and they usually exfoliate in a fortnight. In this severe form it sometimes begins in the legs, and spreads upwards to the loins and navel with a general redness, the cuticle cracking into large pieces; and this will occur every now and then for two or three months. Some children will labour under it till they have cut all their first teeth.

Causes.—In regard to the causes of it, I believe that any little irritation of the alimentary canal will produce it. The irritation of teething, and very frequently exposure to cold, especially if aided by wet, will induce this and various inflammatory diseases of the skin.

Treatment.—In regard, however, to the treatment, whether the disease appear in this aggravated form or not, one of the best things is to give mild purgatives with some alkaline matter, as, for example, a little liq. potassæ, or carbonate of soda, or magnesia, two or three times a day. There is generally speaking an acidity, which may be corrected by something of this description. Moderate aperients can be given at the same time; and the warm bath is found particularly useful. If the disease should prove obstinate, I would certainly give hydr. c. creta.—mercury in a very innocent form; but for the most part it is not required. Great attention should be paid to the diet, for very frequently the disease arises from some little error in that respect, something having been given accidentally, or regularly, which is improper. If the disease suddenly disappear, you may evidently find the child in want of stimuli; and when that is the case, a few drops of liq. ammoniæ, two or three times a day, will be of use, particularly if it be conjoined with the warm bath, and good nutritious food. The warm bath is one of the most important things that can be had recourse to in diseases of the skin, when you want to bring out an erruption or encourage it. I am told that the warm air bath does as well, but I have no experience of it. To avoid cutaneous irritations, nurses should always wash, and not merely dry, infants' napkins.

In this disease, if you should find a pretty active inflammation of the skin, you would, of course, give stronger purgatives, and there might be no harm in applying leeches. If, on the other hand, you found debility, it would be well to give tonics, iron or quinine, and order nutritious diet. You will find that all cutaneous diseases occur in all states of the body; sometimes there is such debility that you will not be able to cure the affection without meat, wine, and porter, and iron, &c. for a time; and in other cases there is an inflammatory state of the body, making it evident that bleeding must be had recourse to and low diet. So in this disease of children, sometimes there is debility of the whole body, the disease continuing because the whole system is out of order; and then better nourishment and tonics will be required. In other cases local bleeding and stronger purgatives will be necessary; but, in general, all that is wanted is a warm bath and alkaline and aperient substances.

In this disease you should be particularly careful that the child is not exposed to cold; it is dangerous to put a sudden stop to the eruption, by allowing the child to catch cold. It is possible that the eruption may cease, and that the child may fall into a state of depression, in which case the warm bath will be required; but it may fall into an internal inflammatory state, and in that case also the warm bath may be useful, but antiphlogistic measures may be required in addition; for when eruptions suddenly cease, there is often an internal inflammation suddenly set up. It is right you should know that these accidents may happen, but for the most part the disease is a mild insignificant affection, more a matter of curiosity, indeed, than any thing else. Here is a representation of the same affections in Rayer's work. It is copied

from Willan, but the diseases are put in a smaller compass.

LICHEN.

The affection which occurs in adults, and is similar to this, is called *lichen*. There is really scarcely any difference in the appearance of these diseases, and I have always been accustomed to consider them as the same, affecting children, and called strophulis; affecting adults and called lichen; and last year, when I read Rayer for the first time, I was glad to find that he entertained the same opinion as myself. I always spoke of them as the same, but I thought I might be wrong; for I do not pretend to be so skilled in these matters as those who have devoted themselves entirely to them; but Rayer says he should unite them were it not for the fear of introducing a new division in the history of papular diseases, which Dr. Willan has described with minute accuracy. It is only from the fear of introducing more confusion, by altering matters as they stand, that he does not treat them as the same disease. I think it had better be done, and we shall simplify the matter at once, and burthen the memory with one disease and set of names the less.

This disease in adults usually occurs in the extremities, and particularly on the outside and posterior parts of the extremities. The papulæ are of the size of the head of a very small pin, and they generally terminate in scurf. The disease is sometimes acute, sometimes recurrent, sometimes chronic, sometimes general, sometimes pretty partial, and sometimes it is connected with internal disease.

Species.—It is divided by authors into simple lichen—*L. simplex*; that which occurs particularly about the roots of hairs—*L. pilaris*; a form in which the papulæ are clustered together—*L. circumscriptus*; and one form very severe indeed, called *L. agrius*. In the simple form you must expect the papulæ to be larger than when they occur in children. If they be very severe, they cluster together; the skin becomes inflamed, and they form deeply red patches. These affections are represented by Rayer: plate 6, first division.

It is said that the simple form of this complaint generally lasts from ten to twenty days. Sometimes there is a smart degree of feverishness, with headache and nausea before it comes out. It is sometimes rather a sharp disease; there is nothing dangerous in it, only that the general excitement is great. It is said that when it occurs about the hairs—*L. pilaris*, it is often chronic. When it occurs in the severe form, called *L. agrius*, there is a great degree of itching, a great degree of heat, and the inflammation is sometimes so violent that you have vesicles and excoriations. This severer form of the disease is sometimes preceded and accompanied by nausea, pain at the stomach, and pain of the head, and may last several weeks, and is much more frequent in women. It corresponds with *Strophulus confertus*. This variety is sometimes connected with a pustular disease, called *impetigo*, but only locally and temporarily; with another, in which serum is secreted—*eczema*; and another in which scales are formed, called *psoriasis*, and sometimes it will degenerate into them.

Sometimes, though rarely, the papulæ are livid, and the variety is called *lichen lividus*; more frequently it is united with petechiæ, or dark spots of congestion. There is one kind of this affection, called *L. tropicus*, which is attended by a great degree of tingling. You will find this mentioned by all writers on the diseases of hot climates, and it is described by them as a most distressing affection. When a person is subject to this variety of the affection, the moment he goes to bed or takes exercise he has a most violent pricking of the skin, called *prickly heat*; and it is called L. tropicus, from the disease occurring in tropical climates. It is not easily repelled, and its sudden cessation is generally the effect, not the cause, of an internal affection. The prickly heat is thought to be a sign of good health. Sometimes the papulæ in this disease are attended with little bumps, like gnat or bug bites; and then it is called *L. urticatus*, affecting the neck and face, particularly in spring and summer, and attended by stinging pain. But though there are bumps or wheals, still there are papulæ. It chiefly affects the neck, face, and hands. It corresponds with *Strophulus candidus*.

Lichen will sometimes be preceded by nausea, vomiting, and pain of the head, and sometimes these will disappear as soon as it comes, and at other times they will continue with it. It sometimes takes place at the end of certain cutaneous diseases; it particularly occurs after fever and catarrh, and it is said even after peritoneal inflammation. Some persons regularly have it annually; some have it at the beginning of the summer, some in autumn, and some are so unfortunate as to have it in both. I know a young lady who has it every spring and every autumn. It was observed by the Romans, and they called it *Sudamina*; and the Greeks noticed it, and called it Ἰδρῶα. In this country, in hot weather, we often have a great tingling of the skin.

Treatment.—Now in all these forms of the disease, the treatment is to be the same as in the strophulus of children. If there be great excitement of the system and headache, one would bleed. If a patient have a strong pulse, even without excitement, you will find that by far the shortest

way is to take a little blood from him, put him on low diet, purge him well, and order him the warm bath. You must not allow the hot bath; for, if you apply much heat to the skin, you will in a great number of cases make matters worse. Just as in the case of children, purgatives, and especially with alkaline matters, given two or three times a day, and low diet, will usually remove the disease. But if the disease be severe, certainly the shortest way is to bleed in the arm in addition; or, if the severity of the disease do not *indicate* this measure, but the constitution of the patient and his pulse, *justify* it, I should still have recourse to it.

For the relief of the parts themselves, which are tingling and itching, you will, I think, find the chlorides of lime and soda answer better than any thing else. Many persons use vinegar for this purpose, which answers pretty well; but I think that in all cases where there is itching of the skin, if that organ be sound, and the chlorides be properly diluted, they are by far the most serviceable. I have known some persons relieved by the application of prussic acid, of the strength of a drachm to eight ounces of water; sometimes more. I had an old man at St. Thomas's hospital lately with great inflammation of the legs, connected with varicose veins, which is certainly not exactly this disease, but nothing relieved him except prussic acid, one ounce to a pint of water. Sometimes, however, this will produce heat and tingling, and it is best not to use at first more than a drachm or two drachms to a pint; but, if this produce no effect, you may increase it; but now and then there is great heat and dryness induced by applying it in a larger quantity. You will find that bleeding at the arm, low diet, and purging, are the best general means, and, as local remedies, either vinegar, prussic acid, or the chlorides, or plain water, warm or cold.

The next disease belonging to this order is Prurigo, and it may easily be mistaken for the itch, but it is not contagious: its consideration, however, I must defer till the next lecture.

CASES TREATED AT THE HOTEL DIEU, PARIS:

WITH CLINICAL OBSERVATIONS,

By M. DUPUYTREN.

Polypi at the back part of the Nostrils—Ligature applied by a new method.

A. Foubert, aged 17, admitted at the Hotel Dieu, July 4, 1832. Ten years previously, he perceived that the right nostril was less pervious to the air than natural, and the left became similarly affected soon after; finally, about a year ago, the passages of both nostrils became completely obliterated, the mouth being constantly kept open in the performance of respiration. Three months before his admission, two ineffectual attempts had been made at another hospital to apply a ligature, and so much irritation had been produced as to have caused constant headache. On examining him, nothing was perceived at the anterior opening of the nostrils. On the right side, neither inspiration nor expiration could be effected in any degree. On the left side he could draw the breath in imperfectly, but could not force it out again at all. The finger, introduced by the mouth, detected, at the back part of the nasal fossa, a polypus about the size of a nut, rather dense and hard: it could be followed to a considerable distance upwards, but without perceiving the pedicle, the situation of which thus remained uncertain.

The patient was taken to the operating-room July 7th, and the following contrivance adopted:—A sound of gum-elastic was introduced into the right nostril, the finger passed into the mouth, into which cavity the point of the instrument was guided. The two ends of a noose of thread were fixed, by means of a knot, to the eye of the sound; the noose was kept open by a spiral spring of brass, like those which are used for braces, and about six lines in length. To this spring, which moved freely on the loop, was attached a coloured thread, the other end of which was also attached to the eye of the sound; so that, in drawing this outwards by the nostril, the loop and the spring were both carried to the back of the throat, where they were easily directed by the finger already there. Lastly, another thread, attached to the loop, and passing out by the mouth, was ready to reconduct it into this cavity, if the attempt at enclosing the polypus did not succeed. While an assistant pulled gently upon the sound, M. Dupuytren, with the left hand introduced to the back of the mouth, tried to slip the noose over the tumor. The first attempt failed, but a second succeeded. The sound was removed, the extremities of the noose kept apart, and by pulling on the thread attached to the spring, which was recognized by its colour, this was brought out, so that the polypus was grasped by the loop of thread alone. The tightening was effected by means of the serre-nœud of Graefe, modified by M. Dupuytren. The thread which remained in the mouth was tied to the serre-nœud. At the end of eight days, gentle pulling brought away the apparatus with the polypus, which was withered, grey, and about the size of an almond.

M. Dupuytren remarked, that the operation of tying polypi in the posterior part of the nostril was one of the most difficult in surgery; the desideratum being some means of keeping the loop open and directing it properly. The simple method above described tends to obviate much of the inconvenience which has hitherto been experienced. Other difficulties are presented by the position of the polypus. When the pedicle is implanted into the base of the skull, it is sufficiently easy to pass the loop round it horizontally, and the same facility is experienced when it is implanted into the floor of the nasal fossæ; but not so when it has its seat on the internal or external wall of the nostril, and when the loop must be maintained perpendicular. When the situation of the pedicle is unknown, of course the trials must be still more uncertain. But besides these, yet more formidable obstacles are presented by the automatic movements of the patient. The finger has to manœuvre on the most irritable and indocile parts, and hence we have constant efforts at coughing, swallowing, vomiting, &c. or the face becomes blue and tumefied, and suffocation is threatened.

In the case above detailed the polypus was not solitary. On the 30th, M. Dupuytren tried to seize another, but was obliged to give it up. On the 10th of August the attempt was renewed with success, but not till the third trial. The patient still continues in the hospital, and it is to be feared that new polypi will continue to spring up, their prevention being even more difficult than their removal. The last remark also applies particularly to the ear, of which the following case affords a good example.

Polypus of the external Auditory Canal — Various Attempts at Extirpation — Renewed Growth of the Tumors.

—— Nezot, aged 50, perceived about two years ago that he did not hear with the right ear. He took a pin to pick out some hardened wax, and after much trouble removed an indurated portion, about the size of a pea. Still, however, he heard no better, and it now appeared that an excrescence filled the tube, which bled when roughly touched, and caused such pain as to make him faint. The polypus was twice removed at St. Dennis, where he resided, but grew again as often; and, at last, Nezot sought relief at the Hotel Dieu, where he was admitted July 13th. On examination, a reddish excrescence was detected in the auditory canal, smooth on its surface, and bathed in pus at its base. The parotid of the same side was much swollen, and the ear seemed as it were lifted up. By these appearances, M. Dupuytren recognized an affection external to the auditory tube, of which the visible polypus was but a symptom: notwithstanding this, however, he thought it right to practise its extirpation. The patient was bled in the first instance, and (July 16) the excrescence was seized with a peculiar pincers, formerly contrived by M. Dupuytren to extract balls, but the polypus gave way under them, and was torn, so that the portion which remained had to be scooped out. The pedicle appeared to be situated at the anterior and superior part of the auditory canal, near the external orifice. Injections of warm decoction of marshmallow were recommended. July 24th, the polypus had reappeared, and was again removed. The region of the parotid was swollen and painful, and though this was relieved by leeching, yet the excrescence appeared again as before, and pus continued to flow, both from the ear and from an opening which formed behind it.

M. Dupuytren observed that the fleshy excrescences which occupy the auditory canal, and to which the name of polypus is indiscriminately applied, may be derived from very different sources: at one time they are true polypi, growing from the skin, as elsewhere they do from mucous membranes, and they are then easy to seize and extirpate, without their renewed growth being apprehended. These cases, according to M. Dupuytren, are the most uncommon. Sometimes they consist of fungous growths originating in an affection of the cellular membrane of the neighbourhood, which first raise the skin, and subsequently perforate it, so as to project externally. Again, they sometimes arise from diseased bone; and, lastly, they may spring from within the tympanum, only becoming apparent when they have ulcerated through that membrane. In these three last cases, it may easily be imagined that no operation directed against the polypus itself can be of avail, for this is but a symptom of the disease, and will renew itself as long as the cause which produces it is suffered to remain. In the present case, the growth evidently proceeded from the cellular membrane, the diagnostic marks of which were the tumefaction and pain of the parotid region, as well as the raising and projection of the ear, which M. Dupuytren had never seen more marked. As to the rest, though it might possibly be but a simple abscess, yet the slowness of its progress was little favourable to this conjecture, and M. Dupuytren, without positively stating so much, seemed nevertheless inclined to the belief that it was carcinomatous. The departure of the patient prevented the point from being determined. Before the extirpation of the supposed polypus, care was taken to practise bloodletting: this, M. Dupuytren remarked, was an important precaution, for the operation is attended with horrible

pain, and the inflammation is apt to spread to the base of the skull, and death, too, often follows. The lecturer observed that he had several times seen this take place, and, indeed, he said that the patient seldom escaped when the inflammation extended from this quarter to the brain. The injections used ought to be moderately warm; if too cold, they are productive of mischief.

Still, however, we have some resources against polypi accessible to the eye or the finger; but there are others which their situation would seem to render incurable: those of the prostate, for instance, which are developed in its middle portion, with or without any pedicle, and which Sir E. Home regarded as an increase of the third lobe of the gland. It has been recommended to cauterize them; but to those who have seen the size that they acquire, this advice will have little value. M. Amussat proposes tying them, but without dissembling the difficulty: once, indeed, he excised such a tumor after the hypogastric operation for stone; but who would venture to open the bladder solely with a view to search for a disease of such obscure diagnosis? M. Leroy d'Etoilles accidentally discovered a method capable not merely of palliating, but sometimes of curing this affection. He introduces into the bladder a bent metallic sound, which is straightened at will by a particular mechanism. The sound thus used compresses the tumor, and the compression is applied for twenty or twenty-five minutes, and repeated at longer or shorter intervals, and thus often re-establishes the flow of urine in a remarkable degree. M. Dupuytren lately employed this plan in a patient at the Hotel Dieu.

Polypus Tumor of the Prostate—Complete retention of Urine—New method of Treatment—Improvement.

An old man, very far advanced in life, and had been long tormented with complete retention of urine. The catheter had been often applied, and with sufficient ease, for the canal was large and offered a free passage, only that a slight difficulty was experienced at the neck of the bladder, as if the prostate were swollen, and the patient made water readily through the instrument; but when this was withdrawn the retention appeared more complete than before. M. Leroy saw the patient with M. Dupuytren, and, suspecting a tumor of the prostate, which applied itself like a valve to the orifice of the bladder, easily explained all the symptoms. The compressing bougie was twice applied; each time about twenty minutes. There was a manifest improvement, but the old gentleman becoming impatient, did not remain long enough to be cured.

CONGENITAL PUBERTY.

To the Editor of the Medical Gazette.

Chichester, Sept. 7, 1832.

Sir,

The accompanying papers have just reached me from America, and as the facts stated in them are worthy of being recorded, I send them to you for publication. I have not the pleasure of knowing the gentleman who has done me the honor to address this communication to me.—I am, Sir,

Your obedient servant,

John Forbes.

To John Forbes, M.D. F.R.S. Physician to the Chichester Infirmary.

New Orleans, State of Louisiana, May 31, 1832.

Sir,—I take the liberty to acquaint you with an extraordinary case of prematurity in a child, which fell under my observation in this city, and request you to communicate the same to the medical society of your city.

Matilda H. was born of a white family in low circumstances, on the 31st of December, 1827. She came into the world with her mammæ perfectly formed, and the mons veneris covered with hairs, as much as a girl between thirteen and fourteen years old. When precisely three years old, the catamenia made their appearance, and have continued to reappear regularly every month until the present time, and as copious as any woman might have them, each period lasting four days. She is now four years and five months old: she measures 42½ inches in height, French measure; her features are regular; she has a rosy complexion; her hair chesnut colour; her eyes bluish grey; she is what may be termed handsome; the conformation of her body is very strong; her mammæ are now of the size of a full-grown orange; and the dimensions of the pelvis are, in my opinion, such as to enable her to bear children when eight years old, and very likely sooner. She constantly enjoys good health.

With sentiments of the greatest consideration, I have the honour to be, sir,

Your most obedient servant,

Justus Ledseau, M.D.

[The accuracy of the details is gua-

ranteed by the signatures of four physicians of New Orleans, and by those of the Mayor, and the British Consul.—E.G.]

LARGE TUMOR OF THE JAW REMOVED BY OPERATION.

[Communicated by Robert Davidson, Esq.]

Abel, a boy of 7 years of age, from the Isle of Rhond, came into the hospital at Little Bacolet, on the 26th November, 1829, with a hard swelling in the left side of the lower jaw, about the size of a hen's egg. Mercurial friction was used, but without any benefit, when he left the hospital.

On the 15th June, 1830, he again returned to the hospital, with the tumor occupying nearly one half of the lower jaw. Mercurial friction, with small doses of calomel, was again had recourse to, but still without any good effect.

June 22, 1831.—The jaw is now immensely enlarged, with an opening behind the canine tooth, from which there is occasionally slight hæmorrhage.

He had hæmorrhage again July 1st, 8th, and also on the 27th and 30th of December: on the 2d of January the hæmorrhage became great, and the tumor rapidly increased; when, after a consultation on the case, an operation was determined on.

On the 17th of January the operation was performed in the following manner:—The boy being placed on a chair, with his head bent a little backwards, the operator, after having extracted the second biscuspidal tooth, made an incision through the lip, half way between the commissure and the angle of the mouth, continuing it downwards over the base of the jaw, and then connecting it with a second, from the lobe of the ear along the base of the tumor. The flap was dissected up, exposing the front of the tumor, and the masseter muscle and adipose substance being removed, the disease was found to occupy both processes of the jaw. The temporal muscle was then detached

and the capsule opened anteriorly. A chain saw, armed with a large needle, was passed behind the jaw opposite the tooth already extracted, and the bone sawed through, the assistant drawing the tumor obliquely outwards. An incision was made close upon the bone, along the inside of the diseased portion of the jaw, separating it from its muscular detachments; the buccinator being cut through at the same time, the tumor was drawn outwards and downwards, so as to allow the capsule of the joint to be divided by a probe-pointed bistoury. The whole was thus removed.

During the operation only two arte-

ries were tied, namely, the lingual and facial, and the hæmorrhage was trifling. The parotid gland had been absorbed, but the masseter muscle was unusually strong and large. The tumor measured seventeen inches and a half in its longest circumference, and twelve inches and a half transversely: it weighed two pounds and a half.

The boy did well, though of course considerable deformity remained, from the extent of the cicatrix. The annexed sketch represents the appearances before the operation.

STATISTICS OF CHOLERA.

To the Editor of the Medical Gazette.

Sir,

In the Number of the Medico-Chirurgical Review just issued from the press, Dr. James Johnson has done me the honour to notice the paper on the "*Statistics of Cholera*," which appeared in your journal of the 11th August. The concluding remarks, so flattering to myself, personally, and for which I feel very grateful, would have restrained me from any reply, but for an anxious desire to mete out that fair measure of justice which the reviewer seems inclined to refuse. I stated "that the amount of deaths then recorded afforded a pretty satisfactory proof that the precautions of government were not unnecessary, and that the anxiety of the public mind had not overstepped the bounds of reason so far as some *philosophers* would induce us to think." Upon this passage the reviewer argues as follows:—"precautionary measures, if they mean any thing, mean preventive measures, and it remains for Dr. Gregory to shew, that these have effected any good, or lessened mortality. Those actually enforced were chiefly quarantine restrictions. The cholera laughed at *them* and their admirers. The precautionary measures adopted were totally inoperative (as all who have eyes in their heads must see) in preventing the rise or progress of cholera, but very operative indeed in inspiring panic, crushing commerce, and heaping additional poverty and distress on a pauperized population."

If all this be true, the government which sanctioned such measures, and the branch of the executive which carried them into effect, have much to answer for; so much, that it is worth while to inquire whether the critic of other's labours is not himself open to criticism and animadversion.

And first, as to the dogma, "that government precautions, *if they mean any thing*, mean *preventive measures*." The government, as a measure of precaution, sent out Sir W. Russell and Sir D. Barry to St. Petersburgh, to investigate the disease. Was this a *preventive* measure? They next established Boards of Health for the purpose of still further investigating the disease, and mitigating, as far as possible, its evils. This is surely any thing but a *preventive* measure. They next carried rapidly through parliament an act for the purpose of facilitating, if necessary, the taxation of the rich for the relief of their poor neighbours suffering under cholera. This was a measure of *precaution*, but not of *prevention*. Preparations were made for the extension of the metropolitan burying-grounds, if unfortunately such a step had been required. Would the reviewer call this a measure of *prevention*. *Et sic de aliis*. So much for the Johnsonian dogma, that precautionary measures, if they mean any thing, mean measures of *prevention*.

And now let me direct the attention of your readers to the second great doctrine propounded by the reviewer: viz. "that the measures of precaution actually adopted by the government not only did no good, but inspired panic, crushed commerce, and heaped additional poverty upon a pauperized population." The latter clause of the sentence is perhaps only one of those high-flown rhetorical flourishes in which the contributors to Dr. James Johnson's journal are wont to indulge; but if meant in sober earnest, I should like to know how Dr. Johnson reconciles it with the enormous sums of money which have been raised by voluntary subscriptions for the benefit of the poor in every district visited by the cholera? In particular, I beg to call Dr. Johnson's attention to the case of Edinburgh, Bilston, and Marylebone, in each of which places many thousand pounds have been charitably given, and most carefully distributed. How is such a statement reconcileable with the fact, that in every place in Great Britain, without exception, visited by the cholera, *gratuitous*

attendance has been afforded to the poor? How does he reconcile it to the fact, of the London Gazette containing from time to time orders from the privy council for the compulsory levying of rates for the benefit of those afflicted with cholera, in places where the inhabitants are backward to assess themselves?

But then, says the reviewer, "the precautions taken by government have *crushed* commerce. Crushing the commerce of Great Britain, in 1832, is rather a strong expression. The writer probably meant to say cramped, or fettered, but even with this emendation, I doubt whether the principal merchants of London and Liverpool would bear the reviewer out. Quarantine regulations, of great strictness, have been in force in England for the last fifty years, and the modifications made to meet the case of cholera were neither very severe nor very long continued. To take an instance, they never affected the price of coals in the port of London. What then is meant by crushing the commerce of England by precautions against cholera?

But the cup of misery is not yet full. These precautions, so obnoxious to the reviewer, "inspired *panic*." Three days of extra quarantine at Hull or Stangate creek, inspire a national panic! This cannot be the meaning of the reviewer, though ten lines previously he acknowledged no precautionary measures of any importance except quarantine. The reviewer undoubtedly means now to allude to the publication of sick returns, tables, and circulars, the formation of local boards of health, and those other precautionary measures which have reference not to prevention, but to the solace of the afflicted poor. And after all, sir, what did the panic amount to, which, according to Dr. J. Johnson, these measures of government inspired? Were our streets, or our churches, or our theatres, or our promenades, deserted even for one day? Did law cease to be administered in places where the epidemic raged not? The fact is, that what the reviewer calls *inspiring panic*, other people call *causing conversation*. People talked about the cholera, but they all knew as well as Dr. Johnson could tell them, that its chief victims were "the poorest of the poor, and the most debauched of the debauched," and therefore there never was a real panic. To the depression of public feeling in such places as Musselburgh, Bilston, Sligo, and Limerick, the reviewer, we presume, would in charity hardly apply the term panic.

I have now, sir, given you my reasons for distrusting the critique with which I have been honoured in Dr. Johnson's journal. I still firmly believe that the precautions taken by government were urgently called for, prudently undertaken, and steadily and judiciously persevered in; and that Great Britain and Ireland have profited by them far more than would have happened, if the public safety had been entrusted to those, who in the columns of the Courier and Times told the people of England, that the Asiatic cholera would be deprived of all its malignity by the variableness of the climate in which they lived.

Dr. Johnson has taken great umbrage at my use of the term *Philosopher*. His concluding words are—"Dr. G. may suppose that nobody likes now-a-days to be called a philosopher." What rational objection can be made to such a designation I am at a loss to comprehend, and least of all by the learned Author of the work entitled "Change of Air, or the Diary of a Philosopher in pursuit of Health and Recreation." It is hard indeed if a man may not call another that which he calls himself.

I am, sir,
Your very obedient servant,
George Gregory.

31, Weymouth-Street,
Sept. 29, 1832.

MORTALITY FROM CHOLERA IN LONDON.

To the Editor of the Medical Gazette.

Sir,

As there is every reason to believe that the cholera is rapidly declining, it becomes a matter of deep interest to ascertain, with as much precision as possible, what is the real extent of the loss which this metropolis has sustained from so dreaded a visitation. The bills of mortality are certainly not free from ambiguity and error; yet they afford the means of arriving at least at an approximate solution of this question. Forty-two weeks have elapsed since the commencement of the current year on the 13th of December, 1831. A comparison be-

tween the burials in that period, and those in the corresponding forty-two weeks of the previous year, as they are reported in the tables of mortality, will not only enable us to form a fair estimate of the degree in which the deaths have increased, but will also show, with tolerable accuracy, to what diseases that increase is to be ascribed.

With this view I have compiled the following table, presenting a view of the aggregate deaths from each disease, between the 14th of December, 1830, and the 4th of October, 1831; and again between the 13th of December, 1831, and the 2d of October, 1832, as they are given in the weekly tables of mortality.

	1831	1832		1831	1832
Abscess	112	144	Hydrophobia	2	2
Age and Debility	1893	2348	Inflammation	1880	2101
Apoplexy	327	359	Inflammation of the Bowels	81	532
Asthma	729	855	Inflammation of the Brain		37
Cancer	59	65	Inflammation of the Lungs and Pleura	13	60
Cholera	35	2973	Insanity	178	141
Childbirth	202	261	Jaundice	33	37
Consumption	3368	3533	Liver, Diseases of	217	267
Constipation of the Bowels	4	23	Locked Jaw	9	8
Convulsions	2066	1611	Measles	532	508
Croup	83	74	Miscarriage	13	18
Dentition		267	Mortification	217	204
Diabetes	6	11	Palsy and Paralytic	166	187
Diarrhœa	15	32	Rheumatism	40	42
Dropsy	659	780	Scrophula	35	16
Dropsy on the Brain	618	669	Small-Pox	436	523
Dropsy on the Chest	78	98	Sore Throat and Quinsey	3	18
Dysentery	8	17	Spasm	3	86
Epilepsy	29	42	Stone and Gravel	12	19
Erysipelas	58	59	Stricture	11	21
Fever	678	700	Thrush	68	93
Fever, Intermittent	17	22	Tumour	9	21
Fever, Scarlet	90	217	Venereal	2	1
Fever, Typhus	141	223	Worms		2
Fistula		2	Unknown causes	7	691
Gout	58	51	Stillborn	637	695
Hæmorrhage	41	50	Casualties	258	370
Heart, Diseases of	88	96			
Hernia	20	30			
Hooping-Cough	1401	489	Total	17745	22843

It would appear on the face of these returns, that the deaths by cholera in the present year have been 2973; but this is undoubtedly far below the truth.

It is universally allowed that the reports of diseases in the bills of mortality are liable to error from the ignorance of the searchers. The searchers form their reports entirely from information derived from the friends of the deceased; and it cannot be questioned, that when the parties are interested in concealing the true cause of death, the real disease will be frequently disguised under some other name which is less calculated to excite apprehension on the part of the neighbours or the public. That these motives often operate in respect to cholera, is matter of daily experience. It becomes, therefore, highly probable that deaths from cholera are frequently concealed under other names, and this expectation is confirmed, if it is found on examination, that those diseases which in their symptoms most nearly resemble cholera, exhibit a very remarkable increase. In this case it is not unreasonable to attribute the excess over the preceding year to cholera.

Under the head of *age and debility* there is an increase of 455, and as this increase has occurred entirely since the middle of March, that is, during the period of the epidemic, there can be little doubt that the vague term of debility has frequently been used to conceal deaths from cholera.

All practitioners are aware that the

symptoms of *inflammation of the bowels*, especially in the early stages, bear a close resemblance to those of cholera, and that hasty and inexperienced observers have often confounded the one disease with the other. On comparing the reports of death from this cause during the two years, we find an increase from 81 to 532. There can be little question that a large part, if not the whole, of the excess, were really cases of cholera.

The term *spasm* seems to have been introduced as an euphemism for cholera. It occurs but once in the bills of 1831. Since February 1832, it has been established as a regular head, and there have been very few weeks in which it has been left blank. The whole excess under this title is 83.

In order to ascertain the real loss by cholera, some account must also be taken of the deaths from *unknown causes*, which have increased from 7 to 691. We are told that this augmentation has chiefly arisen from the dismissal of the searchers in the parish of St. George in the East, so that in the returns from that parish diseases cannot be distinguished. Of course a portion of these undistinguished deaths must have arisen from cholera. If we allow one-sixth, which appears to have been, as nearly as can be estimated, the general proportion in London, an addition will be made on this account of 115.

If these corrections are admitted, the account will stand thus:

Deaths under the head of cholera	2973
Of age and debility . . .	455
Of inflammation of the bowels	451
Of Spasm	83
One-sixth of the unknown .	115
Total . .	4077

This, then, may be taken as the number of the deaths from cholera out of those which are entered in the bills of mortality; but it is far below the whole number in the metropolis.

The burials entered in the bills of mortality do not contain the whole of the deaths even in the parishes which are included in those bills. A large number of individuals, dissenters, and others, are buried in places which are not connected with the company of parish clerks, and therefore do not report. It is stated in the Population Abstract for 1811, that "it was ascertained by the collector of the then tax on burials, that in the last six months of 1794, 3148 persons were interred in the metropolis without being registered, and it is not likely that the whole number of interments, or even of burial grounds, was discoverable for the purpose of taxation." On these grounds the unentered burials in the metropolis are estimated in the above Population Abstract at no less a number than 7000 annually, or about one-third of the whole number at that period reported in the bills of mortality. If, moreover, it is considered that of the parishes themselves many report very irregularly, and some not at all, it will not appear too much to add one-third more for *unentered burials* in the parishes within the bills.

Again, the bills of mortality do not include the whole of the metropolis. The parishes of St. Marylebone, St. Pancras, Paddington, Chelsea, and Kensington, are omitted. By the last population returns, the inhabitants of these omitted parishes are in number very nearly a fourth of those in the districts included in the bills; the aggregate population of the latter being 1,180,502, and that of the former 293,567. One-fourth, therefore, must be added for those parts of the metropolis which are omitted.

On the whole, therefore, the deaths from cholera in London may be estimated as follows:—

Deaths entered in the bills .	4077
Add one-third for unentered	1359
Making the deaths in the parishes within the bills . .	5436
Add one-fourth for parishes omitted	1359
Total	6795

It is probable that some of your readers may object to the above mode of extracting from the weekly bills the number of deaths which have really happened from cholera. They may think the object may be attained more readily and more certainly by comparing the totals; and when they find that the burials in 1832 have exceeded those in the same part of 1831, by 5098, they may inquire why the whole of this excess is not to be attributed to cholera?

But there are sources of error in this reasoning. The reports from the parishes are made with extreme irregularity. The parish authorities, from sheer laziness, often defer their report, not only for weeks, but for months. A large proportion of the deaths of the year are usually brought into the last quarter, and even into the last week. The number of burials reported in the last week of 1831 was no less than 3611. Now the general alarm, and perhaps some awe of the public eye, seem to have partly checked during the current year, this dilatory disposition, so that the reports, though far from regular, are brought up somewhat more closely than usual. The real excess, therefore, of burials is not, as it would appear on the face of the bills, 5098, since that number includes several reports which in the year 1831 were given in at a later period.

That this is a true representation may be shown by a comparison of the christenings. The christenings reported in the first 41 weeks of 1832, considerably exceed those given in the same portion of the previous year; the former being 20,500, while the latter are only 19,178. No adequate reason can be assigned for this excess, except the greater regularity of the reports of the present year. If, therefore, we really wish to compare the totals during the two periods, we must allow for this disparity, and compare the burials of 1832, not with the actual number entered in the bills during the first 42 weeks of 1831, but with this number increased in proportion to the increase of christenings. Thus, if 20,500 christenings had been reported in the first 42 weeks of 1831, the burials would not have been 17,745 but 18,968, and the difference would not be 5098 but 3875 only.

The ultimate result, therefore, would not be greatly altered. It would stand thus:—

Deaths entered in the bills	3875
Add one-third for unentered deaths	1292
	5167
Add one-fourth for parishes omitted	1292
Total deaths from cholera .	6459

Thus, by a different process, we arrive at a result but little differing from that of the previous calculation. It is difficult to say which is most accurate. However, I incline to the larger number, chiefly from observing that the diseases of infants have been much less fatal in the present year. It follows that the total excess will be below the actual ravages of the epidemic.

Whichever number we adopt, it will not appear large, if we take into consideration the vast size of the metropolis. The whole population of London, by the last returns, is 1,474,069. The above mortality will therefore amount to about 4½ in every thousand, or somewhat less than one-half per cent., a rate which is believed to be nearly the lowest which has prevailed in any large town that has been really visited by this malady.

Your obedient servant,

G. G. Babington.

Oct. 4, 1832.

MORTALITY FROM CHOLERA IN PARIS.

Extract of a Letter from M. Moreau de Jonnès, to a Physician in London, dated Paris, Sept. 28, 1832.

"Le nombre des décès dans les tems ordinaires a été surpassé, du 24 Mars au 1er Septembre, de 19,723."

SALINE TREATMENT.

[The following Papers have been transmitted by the Central Board of Health.]

Letter *addressed by the Central Board of Health to the Boards of Health in* Dublin *and* Cork; *with the* Replies *of these Boards.*

Central Board of Health, Council Office, Whitehall, Sept. 11, 1832.

Sir,

On the 5th May last, by order of the Central Board of Health, I enclosed to you a copy of a letter addressed to this Board by Mr. Wakefield, surgeon of the Cold-Bath-Fields Prison in this metropolis, covering details of three cases, in various stages of cholera, treated by the saline powders recommended by Dr. Stevens, with a view to a trial being made of that plan in Ireland.

I am now desired to request, that you

will have the kindness to transmit to me, at your earliest convenience, a short outline of any information you may have obtained as to the result of the saline practice in Ireland.—I am, &c.

(Signed) W. Maclean.

To the Secretary of the Central Board of Health, Dublin.

Do. do. Cork.

Cork Board of Health,
Sept. 18, 1832.

Sir,—I have had the honour to receive your letter of the 11th instant, requesting information as to the result of the saline practice in cases of cholera, and I now beg to enclose for the information of the Central Board of Health of London, the statements of the Medical Secretary attached to this Board, and of the Physicians of the only hospital we have now open for the treatment of this disease, by which you will perceive that the powders recommended by Dr. Stevens have not had the good effects anticipated from them.

I am, &c.

T. Wilson Newsom, Sec.

I have tried the saline powders in many cases, and my experience does not lead me to place much (if any) confidence in their efficacy; at the same time I cannot say that I have seen them produce any inconvenience. The opinions of the medical men whom I have consulted about them, exactly coincide with mine.

P. Kehoe, M.D.
Med. Inspector.

North Cholera Hospital,
Sept. 15, 1832.

Sir,—We have employed, in the treatment of several cases of cholera in this hospital, the saline powders recommended by Dr. Stevens, and have not observed them to produce any good effect. They have, in some instances, caused a great increase of vomiting, but without advantage. We do not think them entitled to any degree of confidence, and have rejected them from the practice of the hospital as entirely useless, if not injurious.

Thomas Casey, M.D.
Denis B. Bullen, M.D.
Physicians to the North Cholera Hospital.

Central Board of Health for Ireland,
Council Office, Dublin Castle, 26th September, 1832.

Sir,—Agreeably to the request contained in your letter, I enclose copies of the opinions of the two superintending physicians of the Cholera Hospitals in Dublin, on the subject of the saline treatment in cholera.

I have the honour to be, &c.

Francis Barker, M.D.
Secretary.

To W. Maclean, Esq.

Cholera Hospital, Townsend-Street,
Dublin, Sept. 24, 1832.

Sir,—In reply to your letter, calling on me for a statement of the results which attended the saline mode of treating the epidemic cholera in the hospital under my care, I have to observe that I and my assistants have employed the above treatment in several cases of cholera, and the only advantage I could ever perceive from its use was an alleviation of the distress produced by vomiting, in some few cases.

I have not, however, found that it was so beneficial as many of the other remedies which we have employed in this hospital with a similar object.

I should observe, that the cases in which I tried the saline treatment were either in collapse or approaching to that state.—I have, &c.

John Hart, M.R.I.A. M.R.C.S.
Superintending Physician at the Depôt Cholera Hospital, Townsend-Street, Dublin.

To Francis Barker, M.D.

Chief Cholera Hospital,
Grange Gorman Lane,
Sept. 17, 1832.

Sir,—In reply to your letter of the 13th instant, inquiring the result of the saline treatment in cholera, (at the hospital under my superintendence), as recommended by Mr. Wakefield, surgeon to the Cold-Bath-fields prison, I have the honour to forward a copy of a letter received from Dr. Falloon, assistant physician to this hospital, who has given the above treatment a fair trial, and I beg to add, that similar results have occurred in the same practice to another of the physicians to the establishment.

I have, &c.

Owen Lindsey, M.D.
Superintendant Physician.

To Francis Barker, M.D.

My dear Sir,—In compliance with your wish, that I should give you the result of my trials of the combination of carb. sod. mur. sod. and oxymur. potassæ, I beg to state that in making these trials I have gone as far as I think any prudent man ought, and the result is, that in the great majority of cholera cases it is not free from hazard. We do want a remedy capable of restoring the powers of life in the really bad cholera, and in supplying this remedy the combination in question is wholly inadequate. I have known it bring on purging when none existed, and in this way hasten, I think, the fatal termination: such is the result of my experience.

I am, &c.

R. Fallon,

Assistant Physician to the Chief Cholera Hospital, Sept. 17, 1832.

To Dr. Lindsey.

CALOMEL—OPIUM—MUSTARD CATAPLASMS OR BLISTERS TO THE EPIGASTRIUM—LEECHES—COLD WATER.

To the Secretary of the Central Board of Health.

Sir,

In compliance with a circular issued by the Central Board of Health, I deem it necessary to trouble you with a brief account of the methods of treatment which I have found most successful in the Cholera Hospital, Nutford-Place, Marylebone.

In those cases in which the stage of collapse was not confirmed, and in which the following symptoms were developed, —viz. rice-water purging, vomiting, pain in the epigastrium, cramps, cold tongue, cold surface, sunken features, areola around the eyes, and suppression of urine, but in which the pulse was of good character, soft, compressible, and about eighty or ninety per minute— I have almost universally found these symptoms yield to the following treatment, recommended, I believe, by Dr. Ayre, of Hull:—One grain of calomel administered every five minutes, with two drops of the tincture of opium, in a dessert spoonful of water. As soon as the purging ceased, I omitted the opium, but continued the calomel until a decided action had been effected upon the liver, indicated by the flow of bile, or until the ptyalism was so profuse that I thought it judicious to withdraw the remedy. I have found that many of the patients, especially those who were previously in a robust state of health, resisted this last effect of calomel, and suffered very little inconvenience from tenderness or ulceration of the gums.

The disease rarely yielded to this treatment until at least seventy or eighty grains of calomel had been prescribed, and it occasionally happened that it was necessary to continue it until the patient had taken more than three hundred grains. In cases which were less severe, I gave the calomel every ten minutes, and in a few instances it was only necessary to give it every fifteen.

It is essential that the calomel should be omitted gradually, as cases of relapse sometimes happened when it was withdrawn altogether, on the first appearance of bile in the evacuations, or when the ptyalism was very copious.

I generally ordered mustard cataplasms or blisters to the epigastrium, which had the effect of allaying the vomiting; and when this symptom could not be subdued by these remedies, the application of twenty-five or thirty leeches most commonly produced the desired effect.

The remainder of the treatment consisted in administering castor-oil about the third day of the attack, which removed the morbid secretion which had been poured out from the internal coat of the intestines during the disease, and which, I think, may be regarded as the cause of the consecutive fever of cholera; for when the tongue was brown, parched, and coated, the skin hot and dry, and the patient anxious and uneasy, in eight or ten hours after the removal of this unhealthy secretion the tongue began to clean, and became moist, the skin was cool, and the perspiration natural.

In cases in which coma supervened, I found leeches applied to the temples, blisters to the scalp and to the nape of the neck, ice to the cerebellum, and large doses of tartar emetic (half a grain or a grain every hour), the most efficient remedies.

The stage of confirmed collapse of cholera I have found much more difficult to put under the influence of medicine. My success has been extremely limited, and most of the cases have

turned out unsatisfactory. In the cases in which the symptoms which I have already enumerated were present, but in which the pulse at the wrist was scarcely to be felt, and in many instances was imperceptible, and the secretions were suspended, I failed in removing the disease by those remedies which were so well adapted for restoring the healthy functions of those patients that came under treatment in the early stage.

The plan I have latterly adopted, and which I have found most successful, is that recommended by Dr. Hardwicke Shute, of Gloucester—viz. copious and frequent draughts of cold water. I have tried this remedy in four cases, and in three instances the patients have recovered. I may mention briefly, that cold water was administered very freely in one case of confirmed collapse, and in eight or ten hours re-action commenced: it was then omitted, and calomel and opium were substituted. Under these remedies the patient relapsed into her previous state, but was relieved again by having recourse to cold water, and she became eventually convalescent without any untoward symptoms.

The house-surgeon, Mr. Toynbee, has been indefatigable in his attention to the patients, and I attribute my success in a great measure to his unwearied exertions. He suffered from a severe attack of cholera about two months ago, but fortunately recovered under the use of calomel and opium. One of the nurses and a porter, who were also attacked, were restored to health by the same remedies.—I remain, &c.

ARTHUR T. HOLROYD, M.D.

12, Harley-Street, Oct. 1, 1832.

BLEEDING — EMETICS — CALOMEL OR BLUE PILL — PURGATIVES.

September 31, 1832.

SIR,

I HAVE received from Mr. De Grace, Secretary to the City of London Board of Health, a circular letter from the Central Board, requesting to know the result of my experience in cholera.

This has been limited, and as to its success, I would prefer leaving any opinion on that subject to the Central Board, when they shall know the circumstances under which I have been placed, rather than pronounce one myself on the subject.

I have had the immediate superintendence of a house belonging to St. Bartholomew's Hospital, which has been appropriated to the reception of such patients of that establishment as might be attacked with cholera, as well as for the poor of the parishes of St. Bartholomew the Greater and the Less; but when cases from other parishes present themselves, which seem likely to prove fatal in the transport to their respective hospitals, by the proper regulations of the Governors they are not to be refused: but I am thus required to admit hopeless cases, while curable ones are rejected.

Since my appointment, 39 cases have been placed under my care: of these, 12 have died, 3 before I saw them, my house being at some short distance from the hospital; 3 still remain, but may be pronounced convalescent; one, however, is labouring under the eruption described as occasionally appearing after cholera.

With regard to the treatment adopted, I should observe, that I make no distinction between those cases in which the dejections may contain some feculent matter or may be tinged with bile, and those which are merely watery; but when I have reason to believe the symptoms present to be owing to the poison of cholera, my practice is immediately to bleed: I then, if collapse appears imminent, give an emetic; afterwards a large dose of calomel or blue pill, followed by purgative medicines: and by this mode of proceeding it affords me satisfaction to state, that no case has been lost which I have had to treat before the system has been drained of its fluids, though the dejections have been characteristic and the aspect highly formidable.

I have thus stated what I presume it is the wish of the Central Board to learn, namely, those measures to which, in my opinion, any certain efficacy is to be attributed, and which I conceive have enabled me, at the institution of which I have had the charge, as well as elsewhere, to check in some instances at once, to mitigate in others, the symptoms of malignant cholera.—I have, &c.

GEORGE LEITH ROUPELL.

7, Caroline-Street, Bedford-Square.

CALOMEL, UNCOMBINED WITH OTHER REMEDIES — MERCURIAL LINIMENT, COMBINED WITH OPIUM, TO THE BOWELS.

September 26, 1832.

SIR,

IN compliance with the request of the Central Board, I beg to offer the subjoined treatment, and to state, that in every case in which it has been employed, success has uniformly attended its exhibition, if the patient was not sunk too much; and even in two cases where the stage of collapse had ensued two hours previously to my being called in, the patients were saved, and have perfectly recovered their former state of health.

In each of the three stages of the disease I have employed calomel, and calomel only, uncombined with opium in any form, convinced as I am, from having witnessed the exhibition of opiates in a multitude of cases, that its effects are most pernicious when administered internally.

The dose of calomel I have given to an adult has been 10 grains every quarter of an hour for the first three hours, 5 grains during the same period in the next three hours, and then continued 2 grain doses every half hour till green evacuations have been procured. In addition to the above, I have given a teaspoonful of sal-volatile every hour in a wine-glass of water, and allowed the patient to drink as much cold water as he wished. Clysters of gruel and common salt have been thrown up the rectum. The bowels over the whole surface have been rubbed every hour with the strong mercurial liniment, and two drachms of powdered opium in every ounce of the liniment. I beg to add that such confidence have I had in the calomel, that the only warmth I have applied has been in the shape of blankets, and a bottle of hot water to the feet, and wherever spasm has ensued I have applied the above-mentioned liniment, and it has yielded to its influence.

There is a boy aged nine years, just recovered under this treatment, who was *comatose* and *pulseless* nearly 14 hours, and should the Board think proper they can refer to the parents for the veracity of my statement. His name is Rigge, 19, Heddon-Street, Regent-Street.

* * * * *

In fine it appears to me, that if medical men would only trust to their own judgment, and draw their conclusions from what actually comes before them, and not be led away by the wild speculations of wilder theorists, who have written without perhaps seeing one single case of this epidemic, I feel confident that they would soon adopt a similar line of practice, by which means very few lives would be lost, and this at present frightful malady would cease to be considered by the public as incurable when the stage of collapse had ensued.

I have the honour to remain, sir,
Your humble servant,

J. H. TAYLOR.

7, Devonshire-Street,
Portland-Place.

CALOMEL AND RHUBARB, WITH CHALK MIXTURE, COMBINED WITH LAUDANUM AND CATECHU, IN THE STAGE OF DIARRHŒA — CALOMEL AND CARBONATE OF SODA IN THE STAGE OF COLLAPSE.

Cholera Hospital, Whitechapel.
September 22, 1832.

SIR,

IN reply to the circular, No. 2, dated Council Office, Sept. 3, 1832, proposing three questions as to our mode of treating cholera in its several stages,—

We beg to state in reply to the first, that we have found a purgative of calomel and rhubarb in the first instance, followed by the chalk mixture combined with laudanum and catechu, generally successful.

Secondly,—we seldom have met with the rice-water evacuations except in the stage of collapse or bordering upon it, when we have treated it as in that state.

Thirdly,—from our more recent experience we have found, from one to two scruples of calomel given directly, followed by ten grains every hour, till the mouth becomes affected, combined with carbonate of soda in the state of effervescence, successful. Ten cases have been treated in this mode, seven of which have recovered, one only being followed by consecutive fever.

We have the honour to be, sir,
Yours very respectfully,

R. J. REED, Surgeon.
J. FAIRBANK, Surgeon.
R. WOODHOUSE, M.D.

ANALYSES & NOTICES OF BOOKS.

" L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

A Dictionary of Practical Medicine; comprising General Pathology, the Nature and Treatment of Diseases, Morbid Structures, and the Disorders especially incidental to Climates, to the Sex, and to the Different Epochs of Life, &c. &c. By JAMES COPLAND, M.D. &c. &c. Part I.

IT is remarkable that we should have been so long without a good Dictionary of Medicine; for *Hooper's* can only be regarded as an explanation of terms; while some of the minor productions in the same class, which have been attempted, consist of wretched imitations or translations from the French, deficient in every requisite, and beneath all criticism. Now, however, we have two important and valuable works in progress — the *Cyclopædia*, which has led the way, and the *Dictionary of Practical Medicine*, which follows. It is generally said, and we believe with truth, that the work which stands second as to the time of its appearance, was first as to its conception, and that it was far advanced ere the elder born was engendered. Certain it is that there were some indications of premature birth about the former, which we do not detect in the latter. Dr. Copland's book bears internal evidence of having been the object of years of labour and investigation, directed to the end in view. The references to the writers of Germany, France, Italy, and England, are countless, and are appended to each article, with indications of chapter and verse, in such a manner as to enable any one to turn to them at once, if he desires further information on the subject. With respect to the manner in which it is got up, the reader will be able to judge for himself, for we find, as this is passing the press, that a specimen of it is to be bound up with the present number, and to which we refer. The subjects treated of are all those falling between "Abdomen" and "Climacteric Disease" inclusive: and not the least praise we have to bestow upon the execution is the just keeping observed in respect to the length of the articles: those which relate to diseases of moment, as "Apoplexy," for example, being fully and elaborately discussed in comprehensive and well-digested essays; while no attempt is made to give consequence to those which are intrinsically unimportant: the author says all that is requisite, and he says no more. The work is a miracle of industry, and forms a fitting companion to the justly-popular *Surgical Dictionary* of Mr. Cooper.

MEDICAL GAZETTE.

Saturday, October 6, 1832.

" Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."
CICERO.

A CHAPTER ON INTRODUCTORIES.

WHAT is an introductory? why an introductory is—but surely all the town must know what it is, after the variety of them that have been delivered in every part of the metropolis during the week. To define the thing is not so easy; perhaps the nearest one can come to it is to say, that it is a lecture to which all manner of persons are admitted, and into which all kinds of subjects are *introduced*. To describe it may be more feasible, or at least to tell what it is like. It is like an Omnibus (as it is also *de omnibus*) that rattles away for an hour over a great deal of space, and is filled with all sorts of company. Or rather it is like a flourish of trumpets: such as that which invites us to the performance of our old favourite, Punch; or which accompanies the "walk in" of the showman, who protests that his wax-works are more natural than life.

We recollect that in days of yore a lecture that went by this name was merely the opening of a course, or perhaps it sometimes went so far as to resemble a good overture, that gave a foretaste of the fine things that were to come; always preserving, however, a suitableness and a due keeping with what was to follow. Matters, it would

seem, are much altered now, and we have heard it remarked, that in these times an opening lecture, to whatever course it may be, is too generally set to one invariable tune—*self and company*, and that the trumpeter enacts the staple of the performance. Of the truth of this remark we were convinced the other day, by one of those odd circumstances which sometimes happen—but perhaps not twice in the same person's life. Having got into one of those very accommodating vehicles above-mentioned, to transfer ourselves—no matter in what direction—our attention was presently attracted by the strange manner of a little bustling gentleman in black, who happened to sit next us. It was evident that he was big with something of which he was eager to be delivered—incoherent phrases were ever and anon bursting from his lips—and his anxiety for the accelerated speed of the omnibus was manifested by a fidgetty restlessness and continual drawing forth of his watch. At length he gave the word to be set down, and made his exit in great haste. In availing ourselves of the vacuum which he left, our eye was attracted by a paper which evidently must have come from his pocket; but it was too late to make any effort to restore it, or to recal the gentleman to whom it belonged. At a glance we perceived what it was all about—the mystery that hung about our recent neighbour was cleared away—the gentleman was a "Professor," and here were we in possession of his introductory lecture. Even at the moment we were decyphering it (which our curiosity immediately prompted us to do), most likely he was already giving it—or all that he could remember of it—to the public; and as by the time the MS. might have been restored through the aid of an advertisement or the bellman, it would have been of use to any one but the owner, we reconciled ourselves to the possession of the document, resolving to make ample restitution in a way that we thought might be agreeable to the author, preserving the original at his service whenever he does us the honour of calling for it. We present a true copy to our readers; it will probably interest those who have not been able to attend any of the introductories during the week, and reconcile them to their disappointment; while it may help the memories of some who have been more fortunate: for we hold it to be an archetype or Platonic idea of all those *omnibus* lectures that we have heard; and thanks to the importunity of our friends, we have heard not a few. It may be well to premise that we have not been able to obtain the most remote knowledge, further than what is above stated, of the learned lecturer who delivered the following address, and though we might suspect several, yet after repeated perusals we can father it identically upon none.

"*Heads of Introductory*, 1832.

"Regret it has fallen to my lot—flattering duty imposed. Importance of our School—the eyes of the country turned upon it—posterity—its fame will throw into shade the Blacks, Cullens, and Monroes, of a certain northern establishment. Not for us to blazon forth our own praise—yet take credit on behalf of learned colleagues—not, perhaps, a more able school in Europe.

"Advantage of having every thing taught under the same roof—concentrate the pupils—dotage of Oxford and Cambridge—disadvantages of those places—subscription—expense—folly of Greek, or of more Latin than the Apothecaries require—*our* mode of managing matters—economy—enlightened spirit of the age.

"Changes which we have in contemplation. *Major rerum nascitur ordo*—

Majus opus. — External distinctions — gowns and caps—with bells or not?—prizes for some—titles for all—difficulty of finding denominations not already engrossed—(a proof of the corruption and monopoly of the old Universities)—propose *Magnus* in Midwifery—*Major* in Surgery—*Maximus* in Medicine—or, all together, *Generals in Practice*—not General Practitioners—probable *value* of our diploma—highly *honourable* at all events.

"Plan for studying universal disease in the whole of animated nature—human pathology illustrated by comparative—proposal to establish a General Hospital properly so called—separate apartments for different classes of animals—but all united—Unity in all things—only money wanted—free to pupils—shame of making those pay who are only learning—Reformed Parliament—*Mem.* Discount to those who attend *all*—and money returned to those rejected.

"Our museum—just a few things—but shall not have time to-day—osteology—splendid drawings—unique preparations—superb wax-works. *Mem.* Must have them all out.

"Few words on medical science—France and Germany—loss of Cuvier—a year big with the fate of great men—allusion to death of Sir W. S.—Shakspeare a great physiologist—knowledge of human nature—'What a piece of work is man! &c.'

"Generous emulation of pupils—genius without industry *flocci nauci*—anecdote of John Hunter—motives from self-ambition—'Knowledge is power,' Lord Bacon, Solomon—credit of the School—fame ultimately on pupils—conduct—most exemplary—never the least riot or disturbance—morality above all things—the great end and aim—value set on character of a *gentleman.*

"Myself—promise nothing—past life and services—professional works—the press—press of business, &c."

The MS. ends abruptly; but we believe there could not have been much more of it. Filled up, as we have no doubt it would have been, had not the learned lecturer dropt it in the omnibus—filled up, we say, with eloquence, and the extemporaneous resources of a fertile mind, such a lecture must have been a splendid production. But what if the loss were uncomfortably felt?—we can hardly think that possible: from what little we had an opportunity of observing in the gentleman's manner, and his emphatic mode of muttering to himself, while his arms moved about, in half unconscious sympathy—we should pronounce him perfectly competent to sustain the loss of his notes. To us, and we fancy to most of our readers, the lecture before us is abundantly intelligible: we can follow, without any difficulty, the whole train of the author's ideas, and we feel that we come from the perusal as thoroughly edified as if the production were swelled into a discourse of above an hour long. Indeed we have sometimes thought that we should prefer to have the lucubrations of certain lecturers given in this form: it would be such a saving of time: but we do not often go to hear lectures,—and what were to become of the pomp and circumstance of the lecture-room on show-days, if such a procedure were to be adopted?

The unknown author of the above notes may possibly regret that they have been given to the public in their unadorned condition, and that he had not had an opportunity of expanding them into a regular essay: but we can assure him that (next to the lucky accident that made us the finders of his MS.) he may consider himself indebted to its brevity for its admission into our pages, especially this week, when we give two lectures at full length.

AMERICAN BOARDS OF HEALTH.

It is curious to observe how frequently republican forms of government, with freedom as their idol, contrive, in some way or other, to display the most arbitrary propensities. Among us there has been, on several occasions, an outery against the attempts of the government to carry into effect the measures requisite for acquiring accurate information as to the extent of the present epidemic, and for staying its progress, although the plans actually adopted have never been more than the necessities of the case obviously pointed out. Our friends in America proceed in a much more summary manner; the most rigid returns are enforced, stating the name and residence of every patient, under heavy penalties; and the power vested in the Boards of Health may be judged of from the resolutions of one of them, which now lies before us, in which any person who has been in a house which a cholera patient has inhabited, and who shall presume to enter the town of Hudson, shall be fined 100 dollars and imprisoned for three months. A pretty strong measure this—we guess. The opinion that the disease is contagious seems to be general, if not universal, in America.

INTRODUCTORY LECTURE

DELIVERED AT THE

OPENING OF THE MEDICAL SCHOOL AT KING'S COLLEGE,

October 1, 1832,

By J. H. Green, Esq.
Professor of Surgery, &c. &c.

[The large theatre was completely filled by persons anxious to hear the Lecture which follows. It was delivered in a most masterly and effective style; and the manner in which it was received, must have been highly gratifying to the feelings of the learned lecturer.]

Gentlemen,—The honour conferred on me by my colleagues, of addressing the School of Medicine as their common representative, has naturally led me to seek for some object in which all the students in the medical and other departments could be supposed to feel a common interest, as members of this College; and presuming that my youthful auditors propose to themselves a scheme of studies, in order to their becoming members of a profession, I appear to myself to have found this common object—this united interest—in the subject of the professional character itself, and of the professions in which it has its various modifications.

A liberal profession may be defined as the application of science, by the actual possessor of the same, to the needs and commodities of social man. The essence of all science is *reason*, manifesting itself in the intelligence of the senses, as in geometry; or in the conceptions of the understanding, as in logic and dialectics; or in the truths of philosophy. And again, as the sciences (or science only, as partaking of the sciences) are so many various parts of one and the same subject—of one and the same spirit—living and growing branches of the same steadfast trunk—it must needs follow, that if the result be one in all, the same unity must be found in the sciences. There are, indeed, many sciences, and they will increase, from an insight into the consequences of distinction; and, with the more intimate knowledge of the objects investigated under the guidance of science, the number of sciences has increased and will continue to increase: still they must all retain the same inherency, the same known and understood derivation, from the common trunk. The root, therefore, of a profession is distinguishable from an art or trade, as a science; and, *vice versâ*, a science becomes a profession by its application to the needs and uses of man, and by availing itself of all the aids of experience and observation in order to this purpose.

In the three great professions—without which society can scarcely be imagined to exist, much less to arrive at or retain any high degree of civilization—the legal, ecclesiastical, and medical, grounded on the corresponding sciences of jurisprudence, theology, and physics, or rather in the history of these professions, as they have at different epochs of the world evolved and matured themselves, there is presented the fullest and most instructive illustration of my meaning—viz. we may trace the necessary connexion of every profession, legitimately so named, with a science, the not to be mistaken manifestation which science gives of its own unity and universality, and the consequent tendency of each particular science, as soon as it becomes explained and realized in an established

profession or order of men, to include in itself the others as yet comparatively in their embryo state, and waiting, as it were, for their full evolution under the protection of the elder. And at the same time, it will be impossible not to trace and admire the evident goodness and predisposing power of a divine Providence, in the order of succession in which the professions have appeared; not to see a great scheme and chain of almighty wisdom in the dependeney of the links, each having its own character, and occupying that place in the chain for which no other could have been a fit substitute. Nor shall I deem either my efforts or your attention wasted, if only I should succeed in leaving on your minds a livelier sense of the natural confraternity of the professions—a clearer conviction of the bands by which they are connected with each other; or, let me add, a more wakeful jealousy of whatever would tend to separate either of the living branches from the science of which it is the fruit and foliage, or those branches themselves from the trunk and root of universal science out of which they spring, and by whose unobstructed sap alone they can obtain the means of life and growth.

As the field must be fenced and cleared of obstructive or noxious growths before it can be cultivated and sown or planted for human use, so man must first be reclaimed to the condition of civilization, must become a member of a community—a citizen. It is evident that law in its largest sense, as including both legislation and the administration of the laws, must have taken precedence of the other professions, and that the science of jurisprudence must have preceded the other sciences.

In Egypt, the first monarchy, the great condition of public law seems first to have been provided in that which supplies the indispensable condition under which alone a people can become a nation—namely, the continuance and continued increase of its civilization; and those conditions are given, and can only be given, in the existence of a learned class, and the provisions for its maintenance. Accordingly we find, that in organizing, as it were, the laws of Egypt into a system of perpetuity, having their source or centre in the individual representative of the whole people, or the monarch, the inspired minister of Pharaoh reserved the revenues of the learned class. The church of Egypt, in the most comprehensive form, was independent and national, and in this manner the materials, as it were, of future science, and of distinct provision, arising from their application, were provided for mankind.

According to the most authentic history, however, it is evident that in Moses the science of legislation first began, and that a legal provision, as grounded thereon, was first established in the institution of the Levites. The Hebrew law was intimately connected with, was a living branch of, a special science—the science, namely, of morality; but of morality considered as a science of the relation of individuals to a community—a science of social obligation, and which must of necessity, in the order of providence, have been antecedent to the science of morality in a yet deeper sense, as respecting the relations and obligations of individuals resulting from the harmony and subordination of that power which in individual man constitutes and contradistinguishes his humanity; I say the administration of the laws, with their application in detail, was entrusted to a distinctly-appointed class, the Levites, whom with truth we may regard as the first profession. Their several residences were determined not by their birth-place, nor by any hereditary possession, but by their functions; their revenues were dependent on the exercise of those functions, and they remained inalienable and national by a primary contract. But most observable it is, and which we shall hereafter have occasion to repeat, so long as the law of science remained in that profession, the unity and universality of science manifested itself. The law, and the legal profession as its outward form, contained and comprehended whatever was known, and in those times capable of development, in both the other professions. The Levites were not only the guardians of the ark and the ministers of the municipal and domestic religion of the state, but they were entrusted likewise with the medical police, and were the inspectors of the public health.

The same proof of my position is supplied equally in the annals of Greece and Rome. The first great names that appear in the dawn of that historical age are those of the great legislators, Minos, Lycurgus, Solon. The first great products of human wisdom were codes of laws. For ages, in Rome at least, the only liberal profession, as distinguished from art and trade, which the free and the noble were honoured in exercising, and the exercise of which constituted a species of nobility, was that of the law; and so it continued as long as the law itself remained a living science—even to the time of Trajan. And when I affirm that the Roman law, which had embodied in itself all the seeds of genial grace, and organized them into a mighty engine of civilization,—when I affirm that this subject, so far as it is preserved in what is called "The Theodosian Code," presents the most perfect form of embodied science, I speak in the presence of those better able to appreciate the truth of the observation

than I myself can pretend to do. But when, in the progress of corruption and degeneracy, the great institutions of the great lawyer were overwhelmed with the whims of immorality, the dictates of insane despotism, and the caprices of individuals, the legal profession soon degenerated into a trade, the members of which were in general probably more feared than honoured.

It cannot, however, but impress a reflecting mind even with religious awe, that the science of the Roman law had not become completed till the conditions had been provided, and the necessity arisen, was felt, and made evident, of a new science calling forth another professional class. The essential character of man had been provided for in the middle form of the state, in order that the individuals partaking thereof might act and work as men. Accordingly the science of legislation, and the legal profession as its living organ, was the first-born and the first matured, and with the excellence that sprung up under its protection, and ripened beneath its fostering influence, came architecture, with the fine arts in the train; and with these again the moral purity of patriotism and local attachment. Thus legislation brought discipline, and the habit of relative duties and functions. These again gave the energy of cohesion to individual citizens, and the power of machinery to the state. But what were the results which the history of Rome records? Conquest, thirst for power, difference of conditions, not only beyond the demands of healthful subordination, but incompatible with and subversive of it—wealth with pauperism, the gigantic shadow which wealth casts on the setting sun of a declining state; then followed sedition, contempt of the past, presumptuous ignorance, and finally, a crazed and dislocated body, clumsily compressed within the iron hoops of military despotism.

Such is the history of the Roman republic,—a mightier power, a more inward and penetrating spirit, than even the spirit of law required—a power which not only, like that of the law, acted from without and on the individual, but which acted primarily and principally *in* the individual, and from within. Such was the condition, and it is but another proof of a special providence in the order of the professions, that these were given and realized in the dispensation of the gospel, and in the chain of providences by which its light was diffused, and its influence collected in the re-radiating foci of widely scattered and increasing churches. But no less, either during the preparation and preparatory to it, was this necessity felt. With the spirit of free law, and with freedom as an emanation from it, the patriotic spirit had likewise departed, and with patriotism, with the co-existence of independent states, with the sense of nationality, all the influence of local and national religion likewise departed, or remained but as the gleams of a phosphorus-drawn image beheld in day-light.

[The learned professor here made an allusion to the mythology of the time, but from the noise of several persons entering the theatre we were unable to catch the import.]

But with the nature and sublime character of this great revolution, to which the anterior history of the civilized world, and the science and profession of the law as its civilizing spirit, was but a preparation for that into which, as the pre-determined centre of providence, all the events in the history of North and South, East and West, had in their awful march been converging — with CHRISTIANITY, as the universal and mundane religion—my subject has no other connexion than as it involves a new profession grounded on science then first made really known.

And it is evident that I here refer to the ecclesiastical profession, and the correspondent sciences of metaphysics and ethics. But let me not be misunderstood. I speak of the profession as grounded exclusively on the correspondent sciences, independently of that higher root which must ever distinguish the ecclesiastical from other professions under a Christian dispensation. It is not of the profession, as an organ of revelation, nor of any branch of the profession which has for its object the preparation of man as a future denizen of another world, that I speak, but of the professions as having generally for their object the maintenance of that progressive civilization without which no temporal state can be either permanent or progressive; and especially the cultivation of the inward man, as to the individual, his integrity, distinct from, though not in separation from, his relation as a fractional part of the state, and his duty as a citizen.

No one can have a livelier sense than myself of the practical evils that accompanied the ever-increasing disposition of the sacred profession to turn from the oracles of inspiration to the schemes or systems descended, or supposed to be descended, from Plato or Aristotle. "Of late," says a contemporary, "do the doctors of the church forget that the heart, the moral nature, was the beginning and the end of their religion, and that truth and knowledge were comprehended in its profession, and that therefore, as preachers of the gospel, they ought to have distinguished themselves from the philosophers of the former world, in whose writings they find the elements of their science, with their metaphysics and logic. Of late, also, in

councils and synods, the divine humanity of the gospel gave way to speculative systems, and religion became a science of shadows, under the name of theology, or at best a bare skeleton of the truth, without life or interest for the majority of mankind, for whom, therefore, there remained only rites and ceremonies, spectacles, bulls, and symbols."

But the fullest persuasion of this truth ought not to blind us to the mighty services which the Jeromes and Augustines rendered in the Western Empire, and the schoolmen who, in the middle ages, and during the whole process of the settlement of the feudal states, effected a barrier in retarding the encroachments of barbarism, in counteracting, and as it were diluting, the thick darkness spreading over the civilized world. Nor let it be forgotten that the scholastic guides prepared the way for the Reformation, and armed the first Reformers with the most effective controversial weapons, and that in the two centuries in which the sciences of theology and ethics reached the highest point; whilst at the same time the Scriptures were most successfully preserved, as the great leaders of civilization, and imparted morals to the profession, which consisted of men whose minds and habits had been reared and formed under the scholastic discipline.

Such, then, was the ecclesiastical profession, and throughout the epoch of its dominant influence it preserved in its own form the unity and spirit of science. The clergy embraced the learned of all denominations, maintained the vital union of all knowledge with the universal sciences, and of all, as having for their common object the preservation, the improvement, and diffusion of the arts and knowledges which constitute the condition, and determine in every country the degree of civilization. And in this, as in the former legislative epoch, the sages and professors of the law and jurisprudence, of medicine and physiology, and even music and architecture, were all alike ecclesiastical doctors and masters of the church.

As it has been my delight to perceive, so it has been my object to prove and display, a predetermined order and providence in the successive evolutions of the third universal profession which is now in its distinct and matured state; and this providence appears to me especially evident in the circumstances that accompanied and led to the third epoch—the evolution of a third branch of a not only distinct but separated profession. In the first epoch we have found all causes working to the formation of the citizen; in the second to the cultivation of the individual as an intellectual and spiritual being; and if a third was to arise, it could only have for its object the relation both to the citizen and the individual man, the nature and the complexion of his dependence on, and intercommunion with, and control over nature; viz. his body. That science of course must be physiology, and the profession by whom the science is, so far as the imperfection of human knowledge permits it to be, applied to the needs of the community, the medical; both terms, physiology and medicine, being taken in the largest sense.

Even a slight acquaintance with the history of our profession will suffice to shew, that its final separation from the ecclesiastic followed the Reformation, or accompanied its dawn when the increasing corruption of the church, the degeneration of metaphysics, and the mis-statements of logic and dialectica had eclipsed the light of experience in all natural knowledge. The astonishing minds of the age felt the necessity of the purer light of revelation to reclaim for the use of mankind the sacred lamp which diffused the whole; the scriptures were once more restored to their place as the foundation of religion, and then the theological, by partaking of this higher principle, became separated as a profession from those of jurisprudence and medicine. Among the earliest efforts we find for the accomplishment of a higher rank of learning, and by which this was effected, one, and not the least important, was the removal of the extravagant overvalue of logic and dialectica, by which, as by a sort of magic, all knowledge was to be obtained of things as well as thoughts. By a great error, the power of logic was not only to succeed, but to supersede reflection, and the consequence was that mere logical facts and generalization were substituted and passed off for the very essence and constituent cause of all things. This delusion gradually, but rapidly, disappeared—this dense fog of human conceit thinned away, and gave admission to the light of experience, and with it to a perception of the necessity of increasing the light by the right use of the senses—the practice of the understanding. The wondrous mechanism of words was now applied to its legitimate purpose, that of communicating knowledge by words, and the acquirement of that knowledge. Reason now acted in its two-fold form, in the pure sense as a metaphysical science, or in the application of sense to experiments or systematic observation. In the future purification of each by the other, about the same time, resulting in part from important discoveries, by a series of providential events of which the most memorable are the compass, printing, gunpowder, and the power of increased vision by the combination of glasses, the world of the senses

was beyond all experience, enlarged, and evolved. New worlds in every direction were opened up for civilized mankind, and under these circumstances the mechanical sciences were rendered available in a thousand directions, at a time that in themselves they received almost miraculous growth and expansion.

Under these auspices physics and physiology became real sciences, not disconnected from pure or formal science which the reason had evolved, but in intimate union therewith, rising from the foresight, and giving rational light and abstractive reality. Then medicine, in the most comprehensive sense, arose to the dignity of a science, and the medical became distinctly and legitimately a profession.

Most true it is that doctors of medicine existed throughout the middle ages, and though the greater part of the art, such as it was, was exercised by ecclesiastics and situated in monasteries, yet as soon as the universities of Europe began to flourish, the teachers and prescribers of medicine were recognised, and degrees of honour given them, under the particular name of *physician* or naturalist. But not less is it true, that during this period the claims of individuals to professional dignity were derived from their connexion with the great seats of learning, and were grounded on their character as men of learning generally, and their connexion not indeed with any science truly worthy of that term, but still with what was then deemed science — astrology, astronomy half metaphysical and half traditional, herbalism, and alchymy. And under the supposition of their connexion with universal science it even then obtained the name and rank of a profession; but in how obscure and imperfect a state, a slight acquaintance with the history of medicine during the middle ages will inform us.

When astrology had faded away before the dawn of true astronomy, and the last dreams of alchymy in the ascending light of chemistry, Harvey, the first great anatomist, arose, and the science extended itself till it received an intelligible practical union with physiology and the laws of life; while at the same time by Boyle, and his associates, the more direct and extended knowledge of the mineral and vegetable kingdom was brought into efficient bearing on practical medicine, and the foundation of a scientific materia medica was laid. The union of science with common sense, the result of observation and experience, found its representative in Sydenham, and immediately after appeared, and all at the same time, three great masters of the profession, each the founder of a separate school, Boerhaave, Hoffman, and Stahl. In these it may be truly said, that the three great divisions of medical science, as having man for its object, might be planted. While the great mind of Boerhaave was happily, though not exclusively, directed to the human body as under the general laws of mechanics or chemistry, so that the iatro-chemical school with all its excellencies and disadvantages may be referred to him as the founder; his no less illustrious cotemporary, Stahl, equally benefitted science in an opposite extreme, in fixing the attention of modern physiologists on the influence of the mind, and demonstrated how large a portion, how important a part of its operations, were carried on without consciousness. But even his clear perception of this great truth led him into the error of confounding will in its most general sense with the mind of the individual, and hence he, as it were, personified both the power and the will by which he connected and identified it with the soul, and thus partially relapsed into the errors of the Helmontian period. But at the same time, as an intermediate stage between Boerhaave and Stahl, the celebrated Hoffman, with less genius perhaps, but with a steadier judgment, laid hold of the great practical truth, that the body to which medical science was to be applied was a *living* body, that the laws and susceptibilities of life should be the main object of investigation, and that the body in all deviations from a healthful state is not to be treated either on the one hand as an hydraulic machine, or on the other hand as a thing merely spiritual and intellectual, on which medicines were to act as by magic spells and incantations. Still, however, in the systems of these illustrious authors, we find all the three great principles constituting the living man; viz. first, the material substance in its connexion with the general laws of fluids and solids, mechanical and chemical, or if we may venture such an expression, the *corporeality* of man. Secondly, the vital principle which characterizes life, and by which the former is modified. And lastly, the mind or intelligent will influencing and controlling both.

It was reserved for our great countryman, John Hunter, almost within our own times, to lay the grounds of harmonizing the third distinction, that life, or the principle of vitality, is the activity of function displayed through organization. This vital principle is necessarily, in order, antecedent to organization, and is its essential condition. But as his theory stands, though perhaps obscurely expressed in his writings, this great man taught this law as the Newtonians taught us to consider gravitation not as a thing, not as spirit, neither as a subtle fluid, but as a law, comprising a specific characteristic. But this was not

all; invaluable as this service was, and most happy as its effects were in the improvement and increased light cast on surgery, he placed the seal on his labours by including the human anatomy in the science of comparative or universal anatomy. He commenced with the rudest forms of organic individuals, and thus supplied both the torch and the materials for his great successors on the Continent, who found in this universal anatomy, the grounds and occasion of a new science, still in its infancy, but in thriving infancy, the science of comparative physiology, and with that the well-grounded and not unconfirmed hope of making every part of organic creation give intelligibility to every other part, and all, to crown the epitome, presented in the human frame.

Had John Hunter performed no other service than that of thus bringing the whole art of healing, medical and chirurgical, into immediate contact with the sciences of nature, which without reference to their immediate practical application, and independent of all professional views, are cultivated by the purest and noblest minds, for their own worth,—if John Hunter had done no more than connect the medical profession with all that is ennobling in science, by a bond of analogy which never, without ignominy to the profession, and the forfeiture of reason, can henceforward be dissolved or broken, he would rightly take his place amongst the most eminent benefactors of mankind, and have left a name which every naturalist must hear with reverence, and which no physician or surgeon can pronounce without gratitude and filial awe.

In directing your attention to the beautiful, and evidently providential order in which the three great professions successively evolved themselves from their several sciences, I find, or rather have already found occasion to make a distinction apparently subtle, but in fact of great historical interest; viz., that between a profession living in a science, and a science continuing to live in the profession. Now the former, that is to say, the profession living in the science, is essential and indispensable to the very being of the profession. Science is the very ingredient, separated from which the compound would cease to be, otherwise than by a misnomer, a profession, and would fall back into an art. But in respect to the latter, the science continuing to live in the profession, there is not only no such necessity, but even the contrary; we may see a proof of enmity and aversion to science contemplated as a vivifying principle. The living principle of science, I say, whichever the science may be, has successively lived in each of the three great professions—yet in one only at the same time; but during this period, the profession in which it lives and acts will necessarily display the essential universality of all sciences, by comprehending in itself, though under its own form, the other two professions. We have seen this exemplified in the science of jurisprudence and profession of the law in the history of Roman jurisprudence. But even an ordinary acquaintance with the history of Rome will supply abundant illustrations of the position of the all-comprehensiveness of the sciences. Theology was admitted to be subordinate to the final cause of the law, shaped and modified according to special purposes, and enjoined and made obligatory, not as religion, not as truth, not as moral goodness, or duty, but as law. And if the medical profession appear less conspicuous, in the form of the Roman law,—and of frequent occurrence it confessedly is—the cause is to be found in the servile employments of medical practitioners, physicians, or surgeons. From Trajan to the age of Justinian, there must have been a period during which the scientific study of the law flourished among professors, though the science itself had ceased to receive growth or access. The profession, however, still lived in the science, and so long it remained honoured; but at length the profession sank, and the very name, throughout a long series of years, became the butt of the vulgar. This arose from the profession itself having fallen into the especial disesteem of mankind at large, and such indeed must, sooner or later, be the fate of every fall from high into lower rank, where the degradation has been effected by the apostacy of the fallen themselves from the essential character and dignity of the rank. It is not only true of the professions, but of the professions it is *especially* true. Language, in all the several dialects of the civilized world, supplies few terms so expressive of contempt and aversion as those which mention the lawyer, the physician, or the clergy, degraded into the petty-fogger, the quack, and the truckling, trading priest.

It is not necessary that I should pursue the illustration through the science and correspondent profession which succeeded to that of the law. It is matter of history known to all, that, with the establishment of the central power in the papacy, the church contained in itself all the sciences in its own characteristic science—metaphysics and logic, in the type of theology; but subordinate to its purposes. The institution of the canon law—the genius and spirit of the new-established kingdom—and, finally, the almost complete occultation of Christian doctrine, sufficiently tell one side of the story; but it would be ungrateful to forget the brighter side of the

question, and omit to mention the schoolmen of Lombardy, the Wickliffes, the Luthers, and Melanethons. The clergy, corrupt as they may have been, were the salt of the earth—were the appointed means who, for generations and generations, conveyed the inextinguishable lamp; and when we take a list of the great men who rose at the constitution of the Augustine monks, we cannot refuse our admiration to a soil capable of bearing such forests of towering trees — as many as the vast cedars of paradise.

Not only did the profession live in the corresponding sciences—as, under the auspicious influence of our not yet subverted institutions, thank heaven! it continues still to do—but until the dynasty of the Tudors the science lived in the profession.

At the reformation arose, grew, and flourished with the other sciences, the study of medicine, purified of material astrology and pseudo-spiritual influence; and with this *pari passu*, a distinct medical profession, the continued advance of which, in the universal estimation of civilized man, has been equally proportioned to the ever closer and closer connexion both of the profession with the science, and of its professors with the growth, progress, and expansion of science. As medical professors, we live in the science of physics and physiology; but likewise with a catalogue of illustrious names alike eminent as naturalists and physicians. The Boerhaaves, and Hoffmans, and Stahls, of successive generations, are ready to acquit me of all boast when I assert that not only the profession lives in the science, but that the science lives and grows in our profession.

Though perhaps less favoured hitherto than our elder sisters, by legislative patronage and national institutions, still the profession is manifestly evolving itself, and putting on a universal and national character; though in each department under its own form. Almost in our own time we have seen a new and distinct science, that of medical jurisprudence, rise, and still in the progress of forming itself: the science of medical police cannot much longer be withheld from the demands of a civilized and commercial nation; and if the benefits already given remain, and those yet wanting shall be supplied, a science of medical ethics will no longer be wanting. I cannot have before me the names and persons of the distinguished cultivators of medical science, whom, with unfeigned humility united with honest pride, I am permitted to name as my colleagues — without perceiving in some perhaps the infancy, but in all the germs of a new department of medical science—a new arena of honourable effort for the medical profession. As surely as man, the epitome of the world's life, subsists in a living intercommunion with all the world, and is destined to act on it by his wealth, his business, and the might of social union, —as surely as the same man, by his animal life, by his imagination, and by the appetites, passions, and affections which arise out of that life, is destined to undergo the re-action of nature and solicit her aidance – so surely I infer the rise, growth, and perfection of a medical botany, a medical chemistry, a medical meteorology, and, I at last hope, a medical psychology; and, thank heaven, we have many points in present view as well as a distinct prospect, if only the realizable condition be not withheld.

Of these conditions, the remaining time allotted to this address will confine me to one most immediately suggested by the place in which I am addressing you. To be an instrument in realizing this condition, has been the main object of this discourse. It has been my aim to prove, first, the vital connexion between each of the professions and the several sciences, especially their corresponding ones, so as to establish the balance between sight and insight, between individual skill and the general principles which determine its application. Secondly, the connexion of each several science, of each profession, with the universal sciences. Thirdly, as the result of both, the primary, the beneficial connexion, the acknowledged fraternity of all the professions with each other; deriving their best honours from the same fraternity, and by every motive of honourable interest and public duty implied and revealed in the protection and furtherance of each other.

Now, to those great and beneficial objects already stated and explained, I have to add the fourth – the connexion of all the professions with those national institutions to which *alone* the name of University can be legitimately applied. Change of time, of circumstances, the increasing number, wealth, demands and qualifications of a nation, will and must direct a corresponding expansion and accommodation of these venerable institutions, and will dictate a well-considered and cautious, but yet not too tardy, increase of their numbers. As, however, the professions of which they are the nursery, and which being many are yet, in their grand and essential constitution, but one, so that, in the common use of terms, it should be indifferent whether they are spoken of in the singular or plural—whether we say national university or national universities—I speak of no mere possibility, no fair, but unrealizable idea. Of this, the very names of Oxford and Cambridge will abundantly serve to acquit me. Each with its characteristic dif-

ferenee; each most honourably marked by the characteristics of its alumni and their own *alma mater*; and still more honourably characterized by their mutual respect; either, thank God, constituted to be the almoners of the whole community. But it is this circumstance which makes the alumni brought up at these institutions feel themselves men of the same class—children of a common household—whenever the occasion of playful comparison between the two is lost in the sense of their common standing. If there be on earth a work worthy of the meditation of the noblest intellect, and to the support of which every motive of philanthropy, patriotism, the love of science, and even the sense of moral beauty can minister, it is to require a practical modification of these institutions, according to their local position and circumstances; and yet, in this variety, to preserve the grounds of their common nature, the condition of their own organization. In this, as in all other human concerns, we must prepare ourselves not to repine at the absence of admitted advantages which the place precludes; much less are we to substitute a counterfeit resemblance for the reality, but seek for a compensation by other advantages which immediate objects prompt and require, and which are in like manner precluded from sister institutions by their peculiar objects. Nor will this, I hope, be found hopeless or unreasonable, if only the great common principle be held sacred—namely, that each university should be truly national, and therefore comprehensive, to the full extent, of the moral needs of a nation. You have in this the very condition of true nationality—viz. the cultivation of men who are to be the fosterers and guardians, and protectors of civilization in all.

In this spirit it is that each university may be expected occasionally to enlarge its possessions by new enclosures. It is in this respect that different universities in the same realm might each, not only without injury, but to the advantage of all, be distinct, and furnish the students, according to their nature, wise and intelligible grounds of preference.

I will venture to illustrate my meaning by a direct application to an institution, the interests of which must, of course, be nearest and most immediate to my own mind and the minds of the present auditory. I should act not only an unworthy part, but, if it were intended to flatter or please the predilections of those that hear me, a most mistaken one, if I undervalued, nay, if I disguised my own convictions of, the peculiar advantages in morals and manners, and the whole formation of the gentleman, which Oxford and Cambridge derive from the temporary domiciliation of the *alumni* within their magnificent halls and colleges—institutions, the beautiful relics of past ages, free from the evil which attached to them under the spiritual dynasty which with us has passed away, and retaining all the good which the existing times either require or expect.

Highly, indeed, do I venerate them in a threefold aspect: first, as honourable asylums of history, literature, and science; secondly, as comprising a great society, ever the same, and who may be considered as a lake, formed by the influx of continuous rills, for all the great services of the realm, and successively poured forth and diversified, to convey light throughout the land; and, lastly, as an intermediate repose,—a few waiting to fill places of the first class, and others preparing, and by the beneficence of past times, enabled to wait, for individual spheres of professional duty appropriated to their talents, acquirements, and character. I know not that we can too highly estimate the advantages to the kingdom at large, the special advantages to the gentry, and whatever is of a liberal nature, from this provision of an intermediate state between the full-grown schoolboy and the independent man—a state during the most perilous period of human life, in which the individual remains *sub tutelâ*, yet no longer as a boy, but as a commencing man, influenced by the character and laws of the institution, and gently coerced by a peculiar discipline, which even at the time he feels to be an honourable distinction, and which he knows hereafter will be considered by others to entitle him to a distinct rank in society. These, and many other advantages from the same source, I distinctly apprehend, and I can, with more perfect freedom from the suspicion of partiality than many of those now hearing could do, declare, that I never hear the names of our two great universities without an increased pride in my country.

These advantages may be incompatible in a metropolitan institution with other advantages of equal moment, which are locally demanded, and by which the former may be in part supplied, or altogether compensated. Numbers, which are of incalculable value, may be mentioned. Much may be done even by the harmonious combination of the preparing school with the maturing university in one system. It induces the alumni of the institution habitually to regard themselves as members of one body—brothers in the same household; to combine a correspondent life of honour, of self-respect, and of respect for each other as fellow-collegians; with the habit of despising the hollowness, the trickery, the ostentation, the littleness, which con-

sists in the ambition of being great to little minds, and the low arts of levying a lucrative tax on ignorance and folly, for the maintenance and thriving of pretended knowledge. In short, that purity of sentiment—that habit of honour and of gentlemanly feeling—in which the moral life of the individual breathes as in its natural atmosphere, with that unconsciousness which gives a charm to unaffected manners and conduct.

Again: the compensating advantages by which this institution may rationally be expected to rise progressively to honour and confidence, are great and evident, and at once correspond and are proportionate to the facilities of its location. And here in an eminent degree we may hope to find the common grounds of professional excellency gradually reduced to the most effective system, even because here the beginning, the end, the root, the stem, and the branches, are composed in one vein, and may be contemplated as a plexus of means to various ends, and united in the same ultimate end. It is possible, and should it prove actual, it will be no subject of regret, that in cultivating the progressive extension of the pure sciences, and in the glorious researches of learning, the elder Universities will take the lead; but, on the other hand, with the knowledge that stands in most immediate connexion with the spirit of the age, with the temporal and physical needs or enrichment of society,—with the external application of this knowledge in all the sciences which have the forms and products of organic and inorganic nature for their material, with the continued application of these to the well-being of the community, as their object in the professions that have arisen, or may arise out of them, and in which the medical profession, in all its various branches, must at all times fill the largest space and occupy the most prominent situation;—I am at a loss to determine which to declare the greater; the peculiar facilities furnished for the improvement of these advantages, and the extent to which the power of participating in them may be augmented in an institution appropriating the means and commanding the resources of this great metropolis, or the necessity and public urgency of providing for the spirit of intellectual expansion and growth which, in some form or other, must exist as a living energy throughout the whole empire. This spirit, we acknowledge, should be connected with whatever is venerable in our native land. We speak of our Alfreds, our Wicklifles, our Cranmers, our Bacons, our Boyles, our Sydenhams, and our Hunters, as beings that still belong to us, as parts of the great organization which their spirits have aided to evolve. It is only by the institution and protection of this and similar great seminaries of learning, in which are cultivated the sciences – anterior to science as connected with the corresponding profession—in the unity of the spirit, under the sense of a common derivation, by the fraternizing habits of a common object; with the members of all the several professions thus acknowledging a common birth-place, which will tend at once to a re-union of all the learned classes; every member of which will be enabled and disposed to regard the progress of another profession as being that of a partner, whose authority and whose influence, whenever rightly directed, he is bound by duty, and prepared by impulse, to support and render effectual.

It would be easy, moreover, to shew the peculiar expediency, nay, moral necessity, of giving to the physical sciences, and the medical as their correspondent profession, a high and important place in a metropolitan university—a university which may become the eye and heart of this great metropolis of the political and commercial world. It would be easy to place this necessity in a still more striking light, could I do it without pain to my own and offence to your feelings, by presenting the full view of the effects and consequences of a contrary plan—of an extensive, active, multiplying profession detached from universal science, and yielding to an ever increasing tendency to empiricism and empirical novelties unsustained by religion, detached from all the institutions that have been the precious birthright of an Englishman. But the picture would be too sombre, and I trust it may be in other countries than our own, that we may be compelled to look for the consequences of professions divided from each other, and having no common bond.

This college has arisen under purer auspices, and I have still faith enough in the English heart of my country to believe that under these auspices, so long as its objects are national, it shall continue to expand and prosper in all its departments. In this belief I utter the name of King's College, and with my heart and soul exclaim—*Esto perpetua!*

ST. BARTHOLOMEW'S HOSPITAL.

To the Editor of the Medical Gazette.

Sir,

Allow me to forward you the following interesting case for insertion in your valuable journal, and remain, sir,

Your obedient servant,

A. M. M'Whinnie.

House Surgeon's Apartments,
St. Bartholomew's Hospital,
October 4, 1832.

Case of "Tremblement Mercuriel," or Mercurial Affection from the process of Gilding, successfully treated by the administration of Conium.

Richard Brown, æt. 35, of spare habit, but good constitution, was admitted, under the care of Mr. Earle, on the 1st of September last. He had been from his youth employed in gilding; from which occupation, however, he had never experienced any disorder, or ill effects, until a fortnight prior to his admission into the hospital, when, after a day of unusually laborious work, he was suddenly seized with cramps in the fingers, which were shortly followed by a shaking and tremulous motion of both upper extremities. They were slight at first, but gradually increased, so as to become very distressing. This agitation of the muscles continued even during sleep, and was accompanied with a gnawing pain, as he expressed it. With the exception of slight pain and heat about the head, his general health was not much affected.

During the first four days, mild purgatives were given him, and leeches, with cold evaporating lotions, applied to the head.

September 6th.—The symptoms have become still more general, the lower extremities having been affected the previous evening, so that, in fact, the whole body appeared in constant motion. The bowels rather costive, but entirely free from pain. Towards the latter part of the day, the tremulous motion of the muscles of the right arm subsided, but the limb remained almost paralysed.

Ordered Ol. Ricini, ℥ss.; Ext. Conii, gr. v. fiat pil. j. ter die sumenda.

From the day on which he commenced the conium, the patient experienced a gradual remission of his symptoms, and at the expiration of about ten days they had almost entirely subsided. At this time, "pilulæ panis" were substituted for the conium, when the patient immediately fell into the same state; the symptoms recurring in perhaps a still more aggravated degree. The conium was again administered, and with its former good effect. He has just left the hospital, apparently quite well. He was, however, recommended to continue the use of the conium for a week or two longer.

SIR W. RUSSELL AND SIR D. BARRY.

Sir W. Russell and Sir D. Barry have just received, through Prince Lieven, diplomas constituting them honorary members of the Imperial Academy of Medicine and Surgery of St. Petersburgh. His Majesty the Emperor had already conferred upon these gentlemen the collar of the order of St. Anne of Russia.

LECTURES

ON THE

THEORY AND PRACTICE OF MEDICINE;

Delivered at the London University,

By Dr. Elliotson.

CUTANEOUS DISEASES.

Lecture II.—Part II.

Papulæ.

I began, gentlemen, at the last lecture, the consideration of diseases of the surface of the body. Among these we began to consider those which are inflammatory; of those which are inflammatory we began to consider a number which are characterized by mere inflammation, without any collection upon the surface of the inflamed part—without any thing contained within the cuticle—without any collection of water, vesicles—without any collection of pus, pustules—without any scales, scabs, or crusts, or any thing else; but those in which we have simple redness of the skin; —and among these we began with those in which the inflammation is exceedingly minute—confined to spots. Of these diseases there are three; the strophulus or red-gum of children, the lichen of adults, and one which has not yet been considered —prurigo.

These affections are all characterized by little, minute, red spots on the skin, called papulæ; which you will recollect are defined by writers on diseases of the skin to be very small acuminated elevations of the cuticle, with an inflamed base, not containing fluid, nor tending to suppuration.

The first of these (the strophulus or red-gum of children) I told you appeared under different forms. Sometimes there is a large number of minute red dots between the papulæ, and then it is called *S. intertinctus.* These minute red dots, not larger than specks, are called *stigmata.* They do not form a disease, but they occur in the midst of other affections, and are called stigmata. Dr. Willan defines them to be bright red specks, without any elevation. In strophulus, lichen, and prurigo, the skin is elevated—there is an acuminated elevation —but in the midst of these you sometimes observe these stigmata. Plate I. contains a good representation of them. I mentioned that sometimes the papulæ of strophulus are white rather than red, and then it is called white gum instead of red gum, *S. albidus.* If these white papulæ be pretty large, and have no inflammation at their base, it is then called *S. candidus*—Plate iii. fig. 3. If they be collected together in any quantity it is called *S. confertus*—Plate iii. fig. 1. Now and then the affection is very evanescent, and then it is called *S. volaticus* —Plate iii. fig. 2. In this form the papulæ are collected in circular patches. I believe I stated that the same disease of strophulus, when it occurs in adults, is called lichen. If this affection occur in the most simple form, it is called *L. simplex*—Plate iv. fig. 1. In a very severe form, it is called *L. agrius*—Plate iv. fig. 2. If the papulæ occur at the root of the hairs, it is called *L. pilaris*—Plate v. fig. 1. If the papulæ are dark, it is called *L. lividus*—Plate v. fig. 2. If the papulæ be collected into patches, regularly circumscribed, it is called *L. circumscriptus*—Plate v. fig. 8. I will only trouble you to remember that these varieties of form will occur; you need not trouble yourselves with the names. I mentioned, that, in hot countries, this disease is sometimes attended with a very high degree of pricking, or burning, without any eruption; and it is then called *L. tropicus.* If the skin be raised into bumps, almost like nettle-rash, it is called

L. urticatus; but then you ought to call it urticaria.

Prurigo.

I will now proceed to the consideration of the last of these three papular diseases. Dr. Willan makes three of them, but you might as well say there are but two. You will remember that not one of these affections is contagious. The disease of which I will now speak is called *prurigo.*

Symptoms.—In prurigo the papulæ are very little discoloured; they are nearly the same colour as the skin, but they are larger than in lichen. They are particularly characterized by itching, and the itching is a far more striking symptom than the eruption itself. That is not the case in the other two varieties, except in that form called *L. tropicus.* In it there is a very severe eruption, whereas here the eruption differs but little from the adjoining skin; and the papulæ also vary from lichen in not being so pointed. So severe is the itching, that people scratch themselves till they rub off the surface of the papulæ, a little blood exudes, (a very minute portion,) and then it forms a little black crust, so that the papulæ will have an artificial black top; and from scratching them water will ooze as well as blood. This, however, is incidental, and has nothing to do with the complaint. If the patient will continue to scratch, he may cause these papulæ to be converted into vesicles; if he scratch still more, suppuration will take place, and he will have pustules; and the skin may be brought into such a state that it will crack and become indurated and hypertrophied. This is a chronic disease; lichen and strophulus are sometimes chronic and sometimes acute; but this usually lasts a considerable time, unless it is properly treated at an early period.

Species.—If it occur in the mildest form, it is called *P. mitis.* This chiefly affects the young. The disease altogether, in every variety, affects both the young and the old; but that called *P. mitis* principally affects the young, and it occurs particularly about the spring or beginning of summer. It is said by some to degenerate into the itch; others, however, deny this. Sometimes the eruption is scarcely visible at all; there is intense itching, but it is rather difficult to find out any eruption. It will remit, but sometimes it will intermit—come and go entirely. If it be very severe, there is an epithet added to the word prurigo to signify great intensity; and, from the itching resembling so much the bite of an ant, it is called *P. formicans,* which is a very severe—I may say a dreadful disease. It affects adults at all periods, but not children; and it occurs in every part of the body except the palms of the hands and the soles of the feet. Occasionally it is preceded by feverishness, pyrexia, by pain of the head, and by sickness. There is a third form, confined to old age, and that is called *P. senilis;* and this is likewise a very severe form of the disease. I should sometimes be at a loss to distinguish between *P. formicans* and *P. senilis,* for the former only occurs in old people. I think it would be better to say that this is a disease which sometimes is mild, but that now and then it is severe. If it attack old people, it generally continues very obstinate for a great length of time. Plate vi. fig. 1. represents *P. mitis;* fig. 2. *P. formicans;* and fig. 3. *P. senilis.* There are no scales, no scabs, no water, no pus.

Now this disease is not dangerous to life, but it is sometimes really a most dreadful disease—dreadful, I mean, so far as suffering is concerned, and, for what I know, it may injure the general health. I have known the intense suffering sometimes cause imbecility of mind. The intense suffering has continued month after month, and indeed year after year, and has produced such depression of spirits, and such exhaustion of mind, that persons have become imbecile, really worn down, and a sort of fatuity has arisen from mere exhaustion. I once had a man come to me at St. Thomas's, when I attended the out patients, in this state. He pulled off his coat, opened his bosom, and shewed me every part in an instant—he was so quick in all his movements. He then pulled a comb from his pocket, and assured me that was the second comb he had bought, having worn out the first in scratching himself. I have no doubt this was true. The itching was most intense, and he had been in this state two or three years, and therefore there had been time to wear out a comb. About three years ago, I had a man who came to the hospital, and whose sufferings had been nearly as intense. The idea had not occurred to him of buying a comb, but he well used his nails in scratching himself. His mind was as much gone as that of the other patient; he was really falling into childishness.

This disease is sometimes local; it attacks a particular part of the body only; is not diffused. It then affects particularly the scrotum of the male and the pudendum of the female. The scrotum from constant irritation, from the patient everlastingly scratching himself, becomes scaly and very much indurated. It will attack the prepuce, and then it is called *P. præputii.* Sometimes it has occurred within the urethra, *P. urethralis.* It will sometimes affect the extremity of the rectum, *P. podicis.* The worst seat of it, however,

is in the pudendum of the female, *P. pudendi muliebris*, and there it is sometimes very violent, very distressing, so that a woman cannot go into society at all; she cannot appear before men, nor can she indeed appear before strange females, in consequence of her being under the necessity of scratching herself. I have known women driven almost mad with the vexation of finding that they were not able to pass five minutes without scratching themselves violently. I saw one woman who was obliged to get up several times in the night, being unable to go to sleep, till at last the heat became so great that she was compelled to get out of bed and wash herself with cold water; and so she had passed every night for months, when I saw her. The vagina and the inner surface of the labia in these cases, when they are very severe, become thickened, and bumps of induration—small indurated portions—are formed here and there: they are not properly tubercles, but have a tuberculated appearance. When this occurs in females, it excites a desire of copulation more and more, and this relieves it for a time, as they have told me, and then in a short time they are worse than ever. It is impossible for them to get relief in this way every moment, and I advised the woman to whose case I had just referred, and who told me that she lived separately from her husband, to use nothing but cold water. It is really, though not dangerous to life, a distressing disease, and women will cry and absolutely wish for death when they are labouring under it. I cannot conceive any thing more lamentable, and, if it occur to a modest woman, it is the most horrid sort of case that can come before you. It rarely occurs in females before the middle period of life. Dr. Willan says, that aphthæ may appear in the anymphæ and internal part of the labia, and be communicated to the glans and internal part of the prepuce of men; but are easily cured, and that they and *P. pudendi mul.* often occur after the fourth month of pregnancy.

The mild form of prurigo may be mistaken for itch: I will not trouble you with the diagnosis now, but advert to it when I speak of itch; I may, however, mention that it will occur in every part of the body; it will occur in the face as well as other parts, but the itch, I believe, will not: and prurigo is not a contagious disease.

Treatment.—With regard to the treatment, however, supposing it to be the mild form of the disease, it is right to make a patient avoid stimuli of every sort—pepper, mustard, wine, beer, &c. Many persons have a tingling immediately on taking certain articles. If I take a grain or two of pepper, or taste vinegar, I have an itching of the scalp, and wherever I am I must begin to scratch my head. If I take opium, I have a violent tingling of the nose for many hours afterwards. Now all these matters, especially mustard and pepper, are likely to increase the affection if it be present. If a patient will bear it, it may be right sometimes to take blood; at any rate it is proper to purge him moderately, and I should advise alkalies, as there is often an acidity in the stomach. But there is a remedy from which I have found greater relief than from any other, not in the mild form only, but in the severe, and one of these men was cured by it, at least he was so far relieved that I could keep him no longer in the hospital, and that is, colchicum. I am sure that if you purge with colchicum, you will find more benefit than from any thing else. In the mild form of the disease, undoubtedly, this is the best remedy. Patients should avoid going near the fire, or taking much exercise, so as to irritate the skin; but I am quite satisfied that colchicum is the best remedy you can employ internally. As to the itching itself, that is very much mitigated by diluted acids, such as vinegar, and also by the chloride of lime or of soda. These produce a very great mitigation of the itching. You will also find relief sometimes from a fomentation of prussic acid. The woman who was so bad from *P. pudendi muliebris*, found great relief for a time from applying prussic acid. She used it at length to such an amount, and of such a degree of strength, that it produced giddiness and fainting, so that she could not stand it, and yet it did not cure her complaint. It appeared at last that the best thing was a cold application, and therefore she had a pail of water brought into her room at night, which she used incessantly. I believe this local prurigo will occasionally arise from some local cause of irritation. Worms in the rectum will produce *P. podicis*: and a stone in the bladder is sometimes attended with a violent itching of the prepuce. In women it sometimes attends structural disease of the womb. It is right to endeavour to ascertain whether there is a local cause, and if there be, you must endeavour to remove it; but, if you cannot find a local cause, then I believe the application of the chlorides, or prussic acid, or cold water, is the best thing. Some tell me that they have seen great relief from what is called the yellow wash—oxymuriate of mercury and lime water. It is much about the same thing as using the chloride of lime. The French use sulphureous baths, and emollient baths containing gelatine, but I have no experience of them.

EXANTHEMATA.

We now proceed to another class of diseases in which the redness is not confined

to spots, but forms patches. Such diseases as these are called *Exanthemata*, or, in English, *Rashes*,—a rash being an extensive redness of the skin.

In these diseases there are not pimples—spots, but patches, the same thing precisely, only of greater extent. They are defined by Dr. Willan to be "red patches, variously figured, in general running together, confluent, and diffused irregularly over the body, leaving interstices of a natural colour, and terminating usually in cuticular exfoliations, though sometimes disappearing without any such exfoliation." The former class of diseases, papulæ, you will remember, either terminated without any thing following, or induced a scurf: these, being a more extended redness, being patches instead of pimples, are followed, not by scurf, but by an exfoliation of the cuticle. Large portions of cuticle separate, and therefore, instead of being branny or scurfy, it is in plates.

These exanthemata often render the surface uneven, by elevating the portions affected. The brightness is variable, and sometimes, Willan says, extravasation occurs.

Now the chief diseases of this description, are, in the first place, erythema and roseola, which I will unite together, or endeavour to do so, as I did lichen and strophulus; the next is measles; the next scarlatina; and then urticaria. Some of these are contagious, and others not. None of the first class were contagious, but two of these are, namely, measles and scarlet fever. These two usually occur but once during life. The two first of these affections are very slight, just like lichen and strophulus, and are not contagious.

Roseola.

The first of these is roseola, and it is merely worth knowing lest you should mistake it for something else. Roseola is described as having rose-coloured patches without wheals, without little bumps, without papulæ, without minute elevations of the skin, and these patches are circular or oval: Plate xxv.

Species.—It occurs at all ages, but especially affects children. When you see children with little rosy patches of the skin, circular or oval, the disease is called *Roseola*. There is an itching sometimes attending it, and sometimes only a tingling. If it occur in children, it is called *R. infantilis*. The patches are of all sizes, and sometimes they are diffused very generally over the body, but if not, still they are pretty numerous. It is a trifling eruption, and seldom lasts more than four or five days. If the patches be round, it is called *R. annulata*. Sometimes there is a little feverishness, a little irritation of the bowels; and those symptoms generally occur from two to seven days before it appears. It is usually a superficial complaint, very innocent to the body, very short in its duration, and after it, there is scarcely any exfoliation. It is said by Rayer, that the character of this eruption is, that, after pressure, the redness returns at all points. In scarlet fever, if you press the rash, the redness, on removing the finger, returns from the circumference of the part; but, in roseola, every part recovers its redness at the same time. I never made the observation myself, and therefore cannot answer for its accuracy. Now and then it might be mistaken for scarlet fever; but, he says, that you may distinguish between the two affections by noticing what I have just stated.

This is a disease of so short a duration that it never becomes chronic unless there be many attacks of it—unless it be remittent. If it come and go, a patient may be troubled with it for a length of time, but the disease never remains incessantly for any long period. In the spring and summer it will no doubt frequently arise from the heat of the weather, but frequently it happens without any evident cause whatever. If it occur in the summer, it is called *R. æstiva*; but if it occur in the autumn, it is then designated *R. autumnalis*. If it occur in small-pox, it is called *R. variolosa*; if in cow-pock, *V. vaccina*. It has various names, just according to these circumstances, which names it is quite nonsense to attempt to remember. Occasionally you will see such rosy patches in continued fever, but still it is called roseola. The redness of the skin which you observe in gout is called roseola. The redness of the skin which you observe in rheumatism sometimes, especially of the fingers, bears the same name. Occasionally the mucous membrane of the throat suffers the same degree of redness, more particularly the pharynx. It would appear that occasionally something of the same nature occurs in the stomach and intestines; at least, when there is this eruption of the body, there will be a violent degree of heat in various parts of the abdomen. After inoculation for small-pox, this little redness will take place before the pustules appear, (they say in one out of fifteen cases,) and inoculators used to imagine that it betokened a mild form of the disease; but if the redness were general and deep, and there were much pyrexia, they supposed it indicated that the disease would be severe—would be confluent. The roseola which occurs in cow-pock, generally appears on the eighth or ninth day.

Treatment.—The disease requires no treatment whatever unless you choose to lower the child's diet, and give it a dose of physic.

You will find this disease represented in Plates xxv. xxvi. xxvii. The great importance of knowing this rash is not to cure it, but to be aware that it is not another disease, because many children have been said to labour under measles, or scarlet fever, when they have only had this redness of the skin. You will hear of children having had measles and scarlet fever half a dozen times, whereas they had merely this little redness of the skin, called roseola.

Erythema.

Now the next disease is separated from it by writers, and called *erythema.*

This disease is said to consist of red patches, or diffused redness, often affecting the subcutaneous tissue, so that there is a little swelling. To shew you the absurdity of distinguishing these two diseases, I may mention that one is called *red patches, variously figured and irregularly diffused*, and the other is called *red patches, or diffused redness.* I am sure it is frequently impossible to distinguish between these two diseases.

The different varieties of erythema are much more unlike each other than many cases of erythema and roseola. All that you have to remember is, that a little redness is called roseola, or erythema; that roseola occurs particularly in infants, and erythema occurs sometimes in rather a severe form.

Species.—It may be transient, and last only about a week, and then there is furfuraceous branny desquamation. Sometimes it is local, and will arise from friction, and then it is called *E. intertrigo.* If the skin be irritated in the groin or arm-pits, the motion of the parts increases the irritation; and if they be accidentally irritated by the dress, then the redness will increase, and this is sometimes called *intertrigo.* However, when this redness is slight, it is called *E. fugax.* If the skin be very smooth, it is called *E. lævе.* If it have a distinct margin, it is named *E. marginatum.* If there be small papulæ, it is designated *E. papulatum.* If, instead of papulæ, you have slightly elevated tubercles, it is called *E. tuberculatum.* If you have large bumps, it is then designated *E. nodosum.* You have seen legs become bumpy and red, and that is an instance of E. nodosum. You also well know, and you will remember, the shining appearance sometimes of an inflamed œdematous leg, and that state is called *E. lævе.* You may as well say that there is erythema with a smooth shining surface, as trouble yourselves to recollect that it is called *E. lævе.*

Causes.—This disease is now and then preceded by a little illness, which disappears when the eruption occurs, and now and then there may be a little feverishness during the attack, but for the most part it is a trifling complaint, or it is consequent upon some other affection. Rayer considers that when there is an internal affection, the disease is the sympathetic effect of the internal irritation—that an irritation of the stomach or intestines is the real cause of the disease, and not that this disease itself is at all capable of affecting the constitution. When persons are out of health, there will be an external inflammation without any contents at all, and that inflammation is called erythema.

But there is a form of this disease which is very obstinate, and you are sure to be consulted upon it. It appears in great patches, chiefly on the legs, and particularly in females. If you draw your fingers along the legs, you will find bumps very hard and red, and it is called *E. nodosum.* Plate xxxii. fig. 1, represents this disease. It is really worth looking at, because it is accurately delineated in this plate. You will be continually consulted respecting it, and asked to give it a name, and if you cannot, you will be considered a goose. Of course patients place the more confidence in you if they fancy you know what is the matter with them, and it is very natural that they should do so. It is very easily cured if treated properly at first; but if it be neglected, it is a very obstinate affection.

Now and then, instead of bumps, you have tubercles, in the common acceptation of the word. This is represented in Plate xxxi. fig. 1. This affection, as I just now said, is called *E. tuberculatum.* You see that these are all superficial rednesses. The tubercles are like peas. It is worth knowing, because patients die when they have it, though I do not know that they die *of* it.

Treatment.—Now the best treatment for this disease is anti-inflammatory; in fact, just the same as for all the others that I have mentioned. If the patient's strength will bear it, you may take away blood with advantage, and you generally find it buffed and cupped. You may also purge the patient; in fact, you may treat him on the antiphlogistic plan: either purge him alone, or bleed him at the arm. If there be anasarca of the legs, you may favour its removal by posture. You cannot expect the erythema to disappear while the leg is hanging down; it arises from the distention of the part; and if the distention of the part be allowed to remain, nothing will remove the erythema. The general rule, however, is to treat erythema as you would any other inflammation.

In the erythema which occurs in the legs of females, you will not only find very

great use from these measures—that is to say, bleeding in the arm, the application of leeches to the neighbourhood of the part, and active purging; but you will find more benefit from colchicum than from any thing else. I have had great experience in the treatment of this disease, and I know the comparative efficacy of combating it by purging with common cathartics, and by purging with colchicum. You will find colchicum the best medicine you can employ, not only in severe prurigo, but in this species of erythema.

I mentioned to you that, in one variety of this affection, there was great redness of the skin, with hard lumps—not so large as in *E. nodosum*, but small lumps about the size of peas, or small-pox pustules. This is a state of the parts which I have never seen but once, and then I confounded it with *E. nodosum*, and thought nothing of it, imagining that I could cure it. The lumps had no sooner disappeared than the man became paralytic, and then hectic, and died in an extraordinary way, with symptoms of various diseases. I was not then aware sufficiently of the distinction of the disease into *E. nodosum*, which is an innocent disease, and into *E. tuberculatum*; but Dr. Willan says that he had seen only three cases of *E. tuberculatum*, and all of them proved fatal. Two of his patients died of hectic, just as mine did, and one died of subsequent hydrocephalus. My patient died hectic, and if he were not hydrocephalic, he had affection within the brain, for he was paralytic. Dr. Bateman says that he never saw the affection.

The treatment, I presume, would be the same as for *E. nodosum*—a certain degree of bleeding and colchicum. I gave it to this man, but to my astonishment he did not get well. Of course, this disease does not give rise to paralysis or hectic, but I presume it is one which only takes place in constitutions which are exceedingly bad—which are strongly disposed to some internal disease, and when the patient is on the eve of labouring under it.

When you see patients with red patches on the skin, of this description, and with scarcely any complaint, you may be sure that the affection is erythema or roseola: call it which ever you please. Now and then you have it very troublesome in females, and with bumps; and now and then you have the tubercular form, which is usually the prelude to a severe and fatal complaint.

The next diseases in this order are very important—measles and scarlet fever; but it is well to get over those which are slight first.

OBSERVATIONS ON PARTURITION.

TAKEN FROM A

Lecture delivered at the Theatre of Anatomy and Medicine, Marsden-Street, Manchester,

October 3, 1832,

By John Roberton,

One of the Surgeons to the Lying-in Hospital.

It has always been the policy of those who decry man-midwifery, to instance the ease and safety of parturition in brutes, and in women amongst savages; and thence to infer, that the same process in civilized society would be equally safe and easy, were it only left (as they contend it ought) to the efforts of nature, and the assistance of matrons. These objectors, it would appear, forget that the practice they recommend was universally followed, in every country in Europe, till little more than a century ago; and that it was gradually abandoned, apparently, through the influence of increasing humanity and intelligence.

The assumed safety of parturition in brutes, of which I shall speak first, involves considerable fallacy. In brutes, it is true, we discover a wonderful degree of perfection in the performance both of the organic and animal functions. But this can be said of them in the wild state only. In that state they rarely exhibit varieties in any respect; that is to say, they very rarely deviate from the primal type of the species to which they belong. In colour, form, habits, and what is of much importance in the present argument, size, they are produced the same in successive generations. In a herd of Bisons, for example, amounting perhaps to many thousands, it is, generally, impossible to detect even a single instance of deviation, in regard to colour, from the natural dun. In our common domesticated animals, a similar uniformity of type is soon produced, when they are turned loose to breed in the wilderness. This is seen in the horses and cattle which the Spaniards, selecting from the various breeds of their own country, introduced into the savannahs of the new world. There they are found, in vast herds, not, as in the domesticated state, of various colour, and size, but of a brown bay—a colour common to a great number of wild quadrupeds; and, in other respects, presenting the uniform features of *feræ naturâ*. These circumstances naturally lead us to infer, that monstrosities, as well as diseases, must be unknown among wild animals — an in-

ference near the truth; yet we shall err, in regard to this point, if we venture to generalise without a careful examination of facts; for although it be true that monstrosities and diseases are extremely rare in wild animals, various instances of both have been known, and were our opportunities of observation greater, probably we should discover more. Camper, a high authority, assures us that he had in his possession specimens of malformation belonging to nearly every species of animal: among others, a gazelle with two heads; also a serpent and a tortoise, each with two heads; and a lizard with the two hinder feet in one. In the great work of Daubenton, examples, I believe, are given of a similar kind. Of the diseases of animals, in their wild state, we are not likely to know much; yet we are not without a number of observations on this point, for which I refer you to the works of Camper. I will merely mention one instance, on the authority of Adair. In the year 1766 an epidemic malady prevailed among the wild beasts, particularly the deer, in the remote woods of West Florida. The Indians, in their winter's hunt, found several lying dead; some in a helpless condition; and others fierce and mad.

The condition of domesticated, is extremely different from that of wild animals. No sooner are the natural habits of animals modified by the influence of man, than a great variety of changes rapidly ensues. Each particular species soon presents, within itself, remarkable diversities, in colour, instinct, figure, and size. They now become liable to numerous diseases; and exhibit likewise almost as great a variety of congenial imperfections as man himself. But of all the organic changes to which they are subject, none is more prominent and worthy of our attention than that which respects the generative system. Frequent sterility now succeeds to uniform fecundity, and abortion, in some species, becomes so frequent, under particular circumstances, that the disposition is even thought to be propagated by a specific contagion. Be this as it may, it often pervades an entire dairy; and is extremely difficult of remedy. So far, again, from bringing forth their young, with uniform ease and safety, the mortality resulting from parturition, under certain circumstances which I shall specify, is incomparatively greater than it is in our own species. And even when the circumstances are of the most favourable kind, this act is attended with more or less pain, and, occasionally, with risk to life.

Without enlarging on the subject of comparative obstetrics, (although I must be permitted to say, that I regard it as one of high interest to the student of midwifery,) it may be well if I make a few remarks, and state one important fact respecting it, derived from a practical person every way worthy of credit*.

Of course those domesticated quadrupeds only, which bring forth one, or not more than two or three young at a birth, call for remark. In such as have a numerous litter, as the sow, the young are individually so small, relative to the size of the mother, as to preclude almost the possibility of causing much difficulty in the birth. Notwithstanding this, I have known parturition fatal to both the cat and the bitch, which, as you know, have a numerous offspring.

It may, I think, be regarded as a law, that the parturient act, in domesticated animals, is easy or otherwise, in proportion as they are subjected to a more or less laborious life. Hence the mare, which is seldom permitted to be idle, rarely dies in parturition. It is in the cow and the sheep, particularly the former, that the act of bringing forth their young is so often attended with difficulty, and even with fatal consequences. In country dairies, where the cow is daily abroad in the open air up to the period of calving, and feeds upon herbage, parturition is comparatively safe and easy; less so, however, I am inclined to think than in mankind; but in town dairies (you are aware that in most great towns very large dairies are kept) the act of parturition is incredibly dangerous, so much so, that it is seldom the dairy proprietor chooses to keep the same cows for more than one year. During each season he sells off his stock, and supplies their places with cows in-calf, purchased from the country farmer; and these he does not admit into his cow-house till they are within eight or ten days of the period of calving. When, on account of her good qualities, he is induced to retain a milch cow year after year, the risk in parturition, and from its consequences, is reckoned equal to one-fourth of the value of the animal.

Thus we find that in town dairies, where the state of the cow is wholly artificial, (that is, where she is never turned out to take either air or exercise, and is fed not on herbage, but chiefly on warm boiled grains,) parturition is attended with extraordinary risk; a risk fifty-fold greater than occurs in the human kind, even under the most unfavourable circumstances that are known.

The next argument on which the opponents of midwifery, as a science, found their objections, is the ease and safety of

* The individual alluded to was for some time the superintendent of a dairy in the neighbourhood of Edinburgh, consisting of about 300 cows.

labour among such savages as the American Indians and the New Hollanders, where, say they, men-midwives are unknown; and woman, like every other animal, brings forth her young by the aid alone of that all-sufficient midwife, nature. Whether or not it be true that women, in this state of society, bear children with more safety than those of our own country, we shall presently inquire. I readily admit, however, that the women of savages experience less pain during parturition, and, comparatively, still less danger and suffering in the puerperal state, than the women of civilization. This is owing to a variety of causes which may easily be pointed out. In a rude condition of society, a great proportion of females, and especially such as are feeble and deformed, are destroyed in infancy. This practice obtains, more or less, in perhaps every tribe of barbarians of whose manners we possess any knowledge. Hence, of course, the healthy, vigorous, and well-formed, alone are reared, and live to become mothers. The life also of women, in such a condition of society, is incredibly hardy and toilsome; and this, by at once invigorating the organic frame, and limiting and repressing the influence of the mind on the body, renders them of a singularly *inirritable* constitution,—almost in the degree of wild animals. Far less sensible to pain than the civilized portion of their sex, they speedily recover from severe wounds, and other bodily injuries, with little or no sympathetic fever. It is of such women as these that James, the scientific narrator of the American expedition from Pittsburgh to the rocky mountains (when speaking of the Indians in their native wilderness) remarks: "During pregnancy the squaw continues her usual avocations, and even in its most advanced stage she neither bears a lighter burden on her back, nor walks a shorter distance in a day, than she otherwise would. If on a march she feels the pains of parturition, she retires to the bushes, throws her burden from her back, and, without any aid, brings the infant into the world. After washing in water, if at hand, or in melted snow, both herself and the infant, she immediately replaces the burden upon her back, weighing perhaps between 60 or 100 pounds, secures her child upon the top of it, protected from the cold by an envelope of bison robe, and thus hurries on to overtake her companions."

If we are to believe many who have lived among barbarians and written of their habits and peculiarities, childbirth in them is uniformly easy and expeditious; nearly as much so as the performance of the simplest of the animal functions. A considerable variety of recent, credible, and highly valuable evidence on this point, however, (furnished chiefly in casual hints and allusions, which is by far the most unexceptionable kind of evidence), leads me to form a very different conclusion. So far is parturition from being *easy, expeditious*, and *safe*, in every instance, we have reason for thinking that *truly difficult* labours are, proportionably, as numerous with them as in our own country. Where there is no malposition of the fœtus, or other impediment, no doubt parturition is a lighter affair with the barbarian than with the European. Of this, speaking generally, there can be no doubt; and the reason I have already briefly stated: but, in exemption from the usual causes of impeded labour, properly requiring the aid of science for the safe and speedy delivery of the patient, I believe there is either no difference at all, or, if there be, it will be found in favour of the greater exemption, from such causes, of women in a state of civilization. The blows and other ill usage in various ways which the women experience at the hands of their husbands, and the heavy burdens which they are in the daily habit of carrying, up to the last hour of utero-gestation, cannot, in all cases, fail in producing either malposition of the fœtus, or injury to the connexion between the fœtus and the mother. Besides, although it be true that few instances of decrepitude, or of other defect in the bony system, are found in a rude state of society, yet there is no doubt that such defects do exist. M. Rollin, surgeon, in the voyage of La Perouse, in his account of the physical peculiarities of the natives of California, assures us that he did not see among them one instance of rickets; and a similar remark is made, by many observers, regarding other barbarians. But what of this? A traveller might visit, and attentively survey, an extensive district of our own country, and behold a far more numerous population than M. Rollin, and the others I have alluded to, saw, and yet, probably, not discover a single case of hunchback, or rickety deformity. As a set off to such sweeping observations of travellers, I may mention a few facts that are brought out, incidentally, in the narratives of some of the most credible authorities we possess, respecting the ruder portion of our species. Thus, when describing the wild tribes bordering on the Rocky Mountains, Mr. James informs us that in the Oto nation they saw a deaf and dumb boy; an adult with a curved spine; and another with an inflexible knee, the leg forming a right angle with the thigh. Among the Kaskias they saw likewise one old woman with a distorted spine, who, Mr. James remarks, when young, had probably suffered from rickets. Scrofula,

the party found, was not uncommon. In Captain Lyon's journal of his voyage to the North Pole, mention is incidentally made of an Esquimaux boy, of five or six years old, who, in addition to mental imbecility, was dumb, had rickets, and epileptic fits. In the account of the missionary voyage of the ship Duff, to Otaheite, (this was at a period when the islanders had as yet borrowed nothing from civilization,) the writer remarks, that a person knock-kneed or bow-legged was rarely to be found. His party saw only three hump-backed children in the whole island, and they were boys. It would, of course, be vain to conjecture how many deformed girls the barbarity of the natives may have consigned to the grave—beyond the observation of the missionaries. In speaking of the natives of Tongataboo, Captain Cook remarks, that they have few natural deformities. He, however, saw two or three with the feet bent inward. By a little more industry in searching for similar facts, others, I dare say, might be discovered; but these are sufficient to demonstrate the probability, that distortion of the pelvic bones may exist in women of even the rudest tribes of whom we possess any knowledge.

But is it really true that barbarian women have always easy and safe parturition? The contrary, I am inclined to think, will be found true. I have already admitted they suffer very little from the effects of labour, just as they would suffer little from a severe accident, or a surgical operation. But in a hundred instances of labour among the Indians of the Rocky Mountains, or the New Hollanders, I see no reason to conclude that the proportion of preternatural cases would be found to be smaller than in Europe: perhaps it would be found to be greater. Although minute and specific information on this point is not to be attained, I have collected a number of remarks more or less directly bearing upon it. Long (a noted fur-trader), in his book entitled "Voyages and Travels among the American Indians," when descanting on the fortitude of the savages, mentions incidentally the fact of a young woman, of the Rat nation, being in labour a day and a night without uttering a groan; the force of example acting so powerfully on her pride as not to allow her to express the pain she felt. Another similar fact is stated in the Voyage of Clarke and Lewis up the Missouri. The wife of an Indian of the party was in labour, and suffering considerably, when one of the Indians gave her as a remedy some of the rattle of the rattle-snake, in powder, pretty much as we should give the ergot of rye. In Hearne's Journal of his Expedition to the Northern Ocean, he casually says, "here (mentioning the name of a place) we were detained two days, owing to one of our women being taken in labour. The instant that the woman was delivered, which was not till she had suffered for near 52 hours, the signal was made for moving." Mackenzie, also, in his well-known Travels in the extreme North of America, incidentally remarks, that, on a particular time, the Indian hunter attached to the party returned, after a temporary absence, accompanied by his wife, leaving behind him his mother-in-law in a helpless state, with three children, and in labour of a fourth. It came out that she had been left "in a state of great danger." In the scientific expedition to the sources of St. Peter's River, its historian, Capt. Keating, states respecting the Potawatomis, a tribe with which he associated for some time, and concerning whose manners his party gained much curious information, that labour was seldom fatal among them, but that many instances had occurred in which the child was so long in being born, that it was putrid when expelled. The same writer informs us, that, in answer to inquiries, made among a tribe of Indians, called Sanks, concerning the usual duration of labour, he was told that the pains of labour continued, in some cases, as long as four days. In general, however, labour continued a very short time. From the Dacotas, another Indian tribe, the same party learned that parturition among them, though generally easy, in some cases lasted from two to four days. In Franklin's Overland Journal, we have another incidental notice of labour in an Indian. A Chipawyan woman fell in labour, in the woods, of her first child, and, on the third day after, died. In Krantz's account of the manners of the Greenlanders, we have an allusion to parturition which deserves mention. He is speaking of the opinions which these savages hold regarding the qualifications that entitle them to gain admission to heaven: among others, those, it appears, find entrance who have been drowned in the sea, or have "died in childbirth."

The next fact I shall mention has reference to a people, the lowest of any in the scale of civilization; I allude to the New Hollanders. Among them a man is not permitted to approach where the act of parturition is being peformed. Collins, an excellent observer and writer, informs us, that he had the curiosity to get a European woman to be present at a native labour. By this person it was remarked, that while one female poured cold water, from time to time, on the abdomen, another was busy performing some trifling charm. How long the labour lasted is not said; but after it was over, the poor woman appeared

much exhausted, and fell across a fire that was in the place, happily without receiving injury.

In concluding the list of facts, in support of this branch of my argument, I have the gratification to present you with what I cannot but regard as valuable and interesting information concerning parturition, as it occurs in the islands of the South Sea, privately furnished me by Mr. Ellis and Mr. Bourne, missionaries, who resided (particularly the latter) a great many years in those islands of the Pacific where missions are established. In order to elicit the information I wanted, in a clear and precise form, I took the liberty of putting in writing the following questions, which I shall give you *seriatim*, with the replies:—

1st, Is parturition, in general, speedier, easier, and safer, in the South Seas, than it is among our own peasantry? Mr. Bourne's reply: — "Parturition in the South Seas is, in general, easy, speedy, and safe, even to astonishment. Immediately after delivery, the women are generally able to arise, take their infants in their arms, and bathe themselves and infants in some neighbouring rivulet. A servant to one of the missionaries, whose business it was to catch and milk her master's goats, was confined with a child on the Sunday evening, and on the Monday morning caught and milked the goats as usual." Additional reply by Mr. Ellis:—"Parturition is remarkably easy. Many instances of this came under our notice. A servant of ours was engaged at washing one morning; labour came on about nine o'clock; she went home; and, in the evening, walking, came again, with the child in her arms. Formerly they used, immediately after delivery, to sit upon a pile of hot stones covered with herbs, and when this had produced profuse perspiration, would rush into the sea within half an hour after. I am disposed to think civilization does make childbearing more difficult, or makes the mothers feel its inconveniences more."

2d, Have very protracted, dangerous, or fatal instances of childbearing come to your knowledge? By Mr. Bourne:—"Protracted, fatal, and dangerous instances of childbearing have come to my knowledge; although such are not very frequent." By Mr. Ellis: — "Protracted and dangerous labours have generally been occasioned by mal-presentations; the most have been shoulder presentations, or the protrusion of the arm."

3d, Have you observed parturition to be more or less difficult according to the state of civilization: easier, for example, in New Zealand than in Otaheite? By Mr. Bourne:—"Parturition is as easy in Tahiti as in New Zealand."

4th, Do the South Sea women employ a class of females, in any respect answering to that of our midwives? By Mr: Bourne: —"No class of women are employed in the South Seas answering to midwives." By Mr. Ellis: — "There were a number of women celebrated for their skill in aiding difficult labours, but in ordinary cases their aid was not sought."

5th, In protracted and difficult labours, what means do they use to hasten delivery? By Mr. Bourne:—"In protracted and difficult labours, no means are used to hasten delivery. Every thing is left to nature. The missionaries have saved many in difficult labours, that otherwise would have died. I knew of one fatal instance, and many others would have occurred but for the missionaries." The reply of Mr. Ellis is in a trifling degree different:—"In difficult labours, the patient was fixed on two stools, while a friend supported the back: or, the patient sat on the extended thighs of an assistant, while another person endeavoured by pressure, and other mechanical means, to promote delivery. We have reason to believe several must have died in childbirth but for the aid of the missionaries."

After so copious an induction of facts, I need say little more, I presume, to convince you that the act of parturition, among the women of rude nations, is not, in the absence of obstetric science, *uniformly* safe and easy: but, on the contrary, notwithstanding the degree of perfection in which the organic functions in general, and of course the uterine, are performed in them (in which respect they are more favoured than the women of civilization), protracted and even fatal labours are at least equally numerous as they are with us.

[To be concluded in our next.]

PROPHYLAXIS OF CHOLERA.

To the Editor of the Medical Gazette.

Sir,

At the present moment, when cholera is infesting almost every part of the United Kingdom, you will not, I am sure, refuse the admission into your valuable journal of any suggestions tending either to mitigate or prevent so fatal a malady. Having had the opportunity of observing this disease in every degree during its progress in Lynn, I have endeavoured to distinguish the juvantia et lædentia, as well dietetic as medicinal. Prior to its visiting us, abundant matter for reflection had

been furnished from many quarters, and numerous modes of treatment had been recommended, but no certain remedy for overcoming the disease when once established was known, and, unfortunately, has not yet been discovered. Under this distressing fact, with a disease so malignant in its character, and so rapid in its progress to a fatal termination, it occurred to me that medical men were not only called upon to pursue their search after means which would remove effectually the horrible collapse—not only to combat all premonitory symptoms—but under certain circumstances to take a step antecedent to this, and *prevent the accession* of premonitory symptoms: I therefore determined on following up this idea, whenever a favourable occasion should present itself.

In July last, cholera made its appearance in that part of the town called North End, where our fishermen reside, a situation above all others considered most conducive to its rapid extension, and there certainly was (judging from the first few cases) an expectation of such a result. Fearing this, and explaining my views to our dispensary surgeon (whose assidnity in this epidemic I am in justice bound to say has been unremitting) I ordered that whenever a case should shew itself, every individual residing in the house, or having communication with the patient or family, should take the following medicine:

℞ Misturæ Cretæ, f. ℥viiss.; Tincturæ Catechu, f. ℥ss.; Olei Menthæ piperitæ guttas, iv. Dosis pro ætate adultâ Cochlearia ii. ampla ter in die.

It will be seen that this medicine presents nothing new, that it is one of every day use to restrain diarrhœa, but the novelty of practice consists in the time of administering it; a time, I grant, very unusual either for a medical man to prescribe, or a person (I cannot say a patient) to take medicine. But, under all circumstances, I consider the practice defensible; whether we look to the great susceptibility of the whole alimentary canal to morbid impressions at this season; to its excessive proneness to diarrhœa whether common or peculiar; or, lastly, to the obtaining a confidence and firmness of mind—a thing very difficult of acquisition at the present juncture. It was, therefore, no small pleasure to find that this last effect was exceedingly conspicuous, and particularly when in addition it became evident to all, that the progress of the disease was immediately and sensibly arrested; and I can adduce many families where a death from the most malignant cholera had taken place in each, without any of the others, who had regularly taken the above medicine, being affected with the disease, or with even its premonitory diarrhœa. I can also exemplify the converse, where nearly whole families have been swept away, who never took any remedial means whatever to prevent an attack. It would be too dogmatic to assert, that the striking suspension on the one hand, and fatal progress on the other, were positively sequences resulting from the use of means on the one side, and a want of them on the other; but there seems great probability of it, and one thing I can aver from numerous cases, and be supported in my averment by the surgeon above-mentioned, that no evil has followed the practice, although the bowels are brought into a more confined state. Having attended a malignant fatal case very closely on the 30th of June, I experienced, on the following morning, a slight relaxation of bowels, with some nausea, and a peculiar sensation about my legs, as though they were paralysed somewhat, and could not perform their duty well, with a tendency to cramp. I immediately procured a cretaceous astringent mixture of a strength greater than the pharmacopœia as regards creta and gum, and have taken it regularly more or less from that hour to the present, without the least inconvenience, except a trifling increase of constipation, which on three occasions only required a simple enema of warm water; purposely avoiding the use of any aperient, from my being in daily attendance on cholera cases. There may be many who will view it in the light of a milk and water practice; others who will deem it a work of supererogation, and quite unnecessary until premonitory diarrhœa makes its appearance, and then will think other means more effective, as calomel and opium, &c. The practice might be mild, but that does not derogate from its efficacy, and I anticipate that a trial of it will be found highly conducive in checking the progress of this most destructive disease. Vaccination we know

to be a mild disease in comparison with small-pox, yet it is a preventive when properly performed and had recourse to in time, but if imperfect, or delayed until the poison of variola has infected the system, it is no longer a preventive.

It forms no part of my present communication to discuss the treatment of cholera, or its contagious or non-contagious character; both of which I may probably consider on an early day, when I have completed a tabular statement of its progress in Lynn; but if not trespassing too much on your pages, I will briefly state my views of the theory of this formidable disease.

* * *

I am of opinion, from the sensations experienced in my own person, since attending cholera patients, as well as from what I have gathered from medical friends under similar circumstances, that the poison producing this disease does enter the bodies of those in close and frequent attendance on the sick, but that it does not exert its baneful influence, to any serious extent, unless the bowels are from some predisposition, or error in diet or regimen, rendered easily susceptible of diarrhœa, and consequently does sooner or later, according to circumstances, lose its virulence, or become eliminated by some other emunctory, either skin or kidneys, and in a way very little, if at all, injurious to the animal economy: otherwise in what way are we to account for the beneficial effects of subduing the premonitory symptoms, which are unquestionably a part of the disease?

During the time this epidemic has prevailed amongst us, the cases of severe diarrhœa, either alone or combined with vomiting, have been exceedingly numerous in the Dispensary practice, at the early period more especially, and these all yielded to the cretaceous astringent medicine alone or united with moderate doses of laudanum, without one particle of mercurial in any form; neither has one case subsequently fallen sick with cholera. I have also learnt from several of my medical friends in extensive practice that the same has obtained with them; one of these, however, prefers the infusum catechu to the cretaceous mixture. There is reason to think that creta is more particularly beneficial and requisite at the present period, for although if it meet with any acid in the alimentary canal, the carbonic acid gas will be disengaged, and some slight flatulence, and perhaps nipping pain, ensue, yet this detracts very little from its utility, because all acids in the primæ viæ should be corrected; and in seasons of cholera the alkali had better be of that kind which will not tend to form soluble purgative salts, and such unquestionably is the carbonate of lime, in preference to the salts of soda or potash. And here let me observe that the excellent chemist, Dr. Prout, has declared that the secretions of our body do now evince increased acid properties. He has found the perspiration exceedingly acid, and also the saliva, which is generally neutral: likewise the lithic acid and lithote deposits to disappear, or be greatly diminished in the urine, and an acid more like oxalic to prevail in it; and the morbid deposits of patients which before were usually compounds of lithic acid, now to be the oxalites. Hence I think we should be still more induced to exhibit chalk freely, as the most preferable antacid, knowing its peculiar efficacy as an antidote to oxalic acid when taken as a poison.

I have the honour to be, sir,
Your obedient servant,
JOHN WAYTE, M.D.

Lynn, September 21, 1832.

DIGEST OF CHOLERA REPORTS PROPOSED.

To the Editor of the Medical Gazette.

SIR,

IT must be admitted, I fear, that no satisfactory pathology of cholera has yet been made out, by means of which the treatment of that disease can be conducted on rational and scientific principles; neither can it be truly said, that the experience hitherto possessed has led to a definite appreciation of the merits of the numerous remedies so far empirically employed.

The pages of your valuable journal, during the last few months, bear ample testimony to the truth of the latter observation; for although cajeput oil and some other remedies, which had received the encomiums of distinguished men, have, by the general consent of the profession, been consigned to oblivion, yet various and contradictory plans of treatment continue to receive the approbation of practitioners; and, in short,

no near approach has yet been made towards an uniform and consistent system of treatment.

The construction of proper returns might, it is conceived, have led, long since, to a more just and decisive estimation of the plans of treatment adopted. The Central Board appears at length to have taken the subject into consideration, and has accordingly distributed circulars, calling for reports of such modes of *treatment as have appeared to practitioners to be successful*. But if what has been previously said be correct, namely, that opposite methods of treatment have all along received and continue to receive the decided preference and commendation of different medical men, what other result can be anticipated from returns regulated by such a principle, than a repetition of the discrepant and embarrassing testimony which the recent records of medicine exhibit? The object which it is desirable to attain is, an accurate comparative estimation of the merits of the plans of treatment adopted under various but accurately-noted modifications of the disease, which can only be effected by a correct, though brief report, of every case returned to the Central Board, with a statement of the remedies, or class of remedies, applied. By returns of this kind the Board would be enabled to construct their own tables, uninfluenced by the prejudices of practitioners in favour of particular remedies. And such impartiality is highly important, for it will be readily granted, that however flattering the result of certain remedies may appear to the medical attendant in a few isolated cases, unless their utility can be shewn by statistic details, in a reduction of the rate of mortality, such utility is, to say the least of it, very problematical.

In prosecuting an inquiry of this nature, a satisfactory result can only be ensured by proceeding upon data as numerous and as closely defined as the subject will admit of—that is, by a brief statement of the *characteristic* symptoms of *every individual case* reported, with the *remedies*, or *class* of *remedies*, employed in it. A statement so particular would be furnished at no great expense of trouble, and a reference to it would remove all doubt concerning the nature and degree of severity of the disease; and thus a repetition of the unpleasant and embarrassing discussions which have occurred relative to the epidemic in Cold-Bath-Fields prison, would be avoided. Any erroneous prejudices entertained in favour of particular remedies, would be exhibited and corrected; as such returns would shew to what extent the rate of mortality was affected by given remedies under defined modifications of the epidemic.

Accuracy of result, however, imperatively requires that the modifications or varieties of the disease, as exhibited in individual cases, should be clearly stated. The general designations, cholera or collapse, are insufficient. The dissimilar rates of mortality exhibited by the reports from different places, are partly explicable, no doubt, by the fact that as there is no strict line of demarcation between the severer forms of *cholerine* (to use a convenient French expression) and the less intense degrees of cholera spasmodica and asphyxia, cases have been made the subject of report from one town which elsewhere have not been considered sufficiently severe to be included. The degrees in the state of collapse are various, and admit of some classified arrangement. Let the characteristics of each case be stated, and then a proper basis for the comparative estimation of the merits of different plans of treatment will be afforded. The characteristics referred to are — extent of serous vomiting and purging; cramps and spasms; temperature as indicated by the thermometer under the tongue; blueness or otherwise of the surface; pulselessness; vox cholerica; ischuria.

If you deem the preceding observations worthy of insertion in the Gazette, I will thank you to give them a place in your next number.—I am, sir,

Your respectful and
obedient servant,
R. Arrowsmith, M.D.

Coventry, September 22, 1832.

P. S. — *Sulphate of Manganese.* — The absence of bile in the discharges from the alimentary canal, in cholera, has been every where remarked upon, and it has been almost as commonly stated that the re-appearance of this fluid in the discharges is a proof of the subsidence of the peculiar morbid action. But whether such re-establishment of biliary excretion is to be regarded as the

cause or as the mere sign of improvement, has not been stated. One writer conceives "that the blood of the portal veins is charged with the choleric miasm;" another remarks, that "small doses (of calomel) have been really efficacious in restoring the secretion of bile, and *thereby* promoting the *decarbonization* of the blood;" and scarcely has a practical paper on the effects of remedies been published which does not contain some allusion to the important beneficial consequences of the re-appearance of bile in the discharges.

These remarks are designed as merely introductory to the mention of a remedy as yet untried in practical medicine, but which can scarcely be an indifferent one in several morbid conditions. I allude to the *sulphate of manganese*. All the knowledge I have of this substance is derived from a passage in Marx's Toxicology, and which passage is, in fact, a quotation from Gmelin's Experimental Treatise on certain Mineral Poisons. The passage referred to states, that the sulphate of manganese, when injected into the veins (the experiments were performed on rabbits, I believe), produces a striking action on the liver, increasing the secretion of bile in an extraordinary degree, so that the large vessels were coloured by it; and even causing inflammation of the liver. If the therapeutic agency of this sulphate be found to accord with its reputed physiological action, it may prove a remedy of utility—if not in cholera, at all events in some other states of disease.

SUCCESSFUL EMPLOYMENT OF SALINES AT THE CHOLERA HOSPITAL, ST. LUKE'S.

To the Editor of the Medical Gazette.

Sir,

Government having required information concerning the different modes of treatment adopted by medical gentlemen who have had opportunities of attending patients labouring under the Asiatic or spasmodic cholera, I have drawn up a report for the Central Board, and beg to send you the following brief communication for your journal.

Having, since the month of June, been engaged in attending upon cases of this character at a public institution, I have naturally felt extremely anxious to avail myself of every source of information I could obtain.

The sphere of my practice has been extensive; comprising, not only such patients as were received into the hospital, but such also as were out-patients in a large and extensive parish in the metropolis.

I soon found, upon conversing with several respectable practitioners in the neighbourhood, that a variety of conjectures had, as usual, been formed, concerning the nature of the new epidemic; and, consequently, a diversity of opinions existed as to the most effective method of cure.

Under this perplexity, from the discordance of sentiments entertained by intelligent professional men, I was induced to pursue that mode of treatment which had been previously adopted by those gentlemen who had been in the daily habit of attending and prescribing for the sick; consisting chiefly of calomel and opium, which were exhibited conformably to the symptoms and urgency of the case, and which, I believe, were deemed the best remedies in general use.

But finding much disappointment in pursuing this plan, and considering it as merely combating with the symptoms of the disease, instead of striking at the root of the malady, I abandoned the pursuit, and adopted that mode of treatment denominated the *saline*, in the manner laid down and recommended by Dr. Stevens, in his recent publication on "The Healthy and Diseased Properties of the Blood;" and, in as far as relates to cholera, I am decidedly of opinion, from my own personal observations and experience in the treatment of this direful disease, that the saline remedies are not only the most rational, but decidedly the most successful that have yet been tried; and, from what I have seen of their effects, I am induced to believe that they demand the attentive consideration and practical *test* of the profession, in preference to remedies which have been extensively used with so little advantage.—I am, sir,

Your most obedient servant,

S. Cambridge, M.D.

Cholera Hospital, St. Luke's,
City Road, Oct. 2, 1832.

SUPERIORITY OF THE SALINE TREATMENT.

Report from Greville-street Hospital.

To the Editor of the Medical Gazette.

Sir,

Now that the epidemic named cholera has existed for some time, and still continues its ravages in various parts of the kingdom, and as no uniform and successful mode of practice has yet been laid down either by the Central Board of Health or any other constituted authority; from the experience I have had I feel it my duty, alike for the advancement of medical science as well as for the public benefit, briefly to report the cases that have occurred, with their mode of treatment, at this hospital; leaving unbiassed practitioners to draw their own conclusions as to the merit (if any there be) of the plans which have been used for arresting the very fatal termination of this appalling disease. Allow me, in the first place, to remark that this hospital is not under the control of any Board of Health, but perfectly independent; its doors have been, and still are, open to every destitute and diseased individual, of whatever cast or country; the only letter of recommendation required, being "disease and poverty." Under such circumstances, it is evident that the most wretched outcasts from various parts of London, when seized with this disorder, have been brought in; likewise a great proportion of the patients have been sent in, I might say, to die, inasmuch as they had been treated, but abandoned as hopeless, by the medical officers of surrounding parishes. The hospital is equally free to every professional and scientific individual; by which an opportunity is afforded to every person so disposed of watching both the progress of the disease and the result of treatment in every patient. Sir, in forwarding to you the following list of patients and mode of treatment, I must beg to be distinctly understood that it is with no other motive than to make known, through the medium of your journal, to the profession in various and distant parts of the kingdom, a system of treatment that has been pursued here with more uniform success than at any other hospital in this metropolis.

For practical purposes, I have thought it advisable to divide the progress of this disease into two stages, although varieties occasionally occur that would defy any order or classification, but for the most part the diagnostics are well defined. The Central Board have marked out three stages of the malady; have likewise advised a very complicated mode of treatment. Simplicity of arrangement and treatment are of the utmost importance to practitioners, who are yet but little acquainted with the nature of the complaint. The first stage, I mark as continuing up to a period when the functions of the liver and kidneys may by artificial means be excited; hence the importance of calomel. The second stage to commence when the pulse is imperceptible at the wrist, and when the liver and kidneys cease to act, and cannot be stimulated to action by any known remedy until the patient is freed from the specific poison, and the volume of circulating fluid be in some degree restored. In general, one or two doses of calomel have been found to excite sufficient gastric and renal action to drain from the blood the morbid poison, but when the patient is not seen before the second stage ensues, from twelve to twenty-four, or forty-eight hours, is in general the period before re-action can be established by the saline plan of treatment: but in children the effects are more immediate. It is my opinion, that the quantity of fluid drained from the blood into the stomach and intestines is the specific effect of this peculiar poison, and that the vomiting and purging are the consequent results of the immense accumulation of that fluid in those organs, and that both actions are absolutely necessary for the well-being of the patient. Two patients have been cured by saline injections, after all hopes of recovery from the saline medicine were lost: one treated by myself, the other by Mr. Reynolds, surgeon, of Carsharlton, a gentleman who has diligently watched the results of the saline treatment at this hospital. The extreme thirst indicates the indispensable supply of fluid. One patient, who died under the saline treatment, swallowed no less than forty gallons of water in ninety-six hours: during the first twelve hours after his admission, he took seventy-eight pints.

Ten patients, who are now quite restored to health, took no less than 225 gallons of water within seventy-eight hours.

Remedies during the First Stage, up to four years of age.

Calomel, 5 grains; Ginger, 5 grains. Mixed together for a dose.

This powder to be given immediately, mixed in a little treacle; and two hours after the powder, give the following draught:—

Powdered Rhubarb, 10 grains; Castor Oil, half an ounce. Mixed together, and given in half a cup of strong coffee.

Should the vomiting and purging continue, give two table-spoonfuls of soda water every half-hour, and repeat the powder of calomel and ginger four hours after the draught.

From the age of four years to fourteen, give the following powder and draught:—

Calomel, 9 grs.; Ginger, 9 grs. Mixed.

The draught:—

Castor Oil, three quarters of an ounce; Tincture of Rhubarb, two drachms; Powdered Rhubarb, 8 grs. Mixed.

From the age of fourteen and upwards, the following powder and draught:—

Calomel, 15 grs. to 20; Ginger, 15 grs. to 20. Mixed.

The draught:—

Castor Oil and Tincture of Rhubarb, of each one ounce. Mixed.

Small draughts of soda water to be taken by all, providing the vomiting continues; and should the symptoms not abate, the powder and draught may be repeated four hours after the first dose.

Remedies during the Second Stage.

No. 1.—Up to the age of 4 years:—

Common Salt, one scruple; Carbonate of Soda, six grains; Oxymuriate of Potash, two grains. Mix for one dose.

No. 2.—From 4 to 14 years of age:—

Common Salt, one drachm; Carbonate of Soda, ten grains; Oxymuriate of Potash, three grains. Mix.

No. 3.—Above the age of 14 years:—

Common Salt, two drachms; Carbonate of Soda, one scruple; Oxymuriate of Potash, seven grains. Mix.

The above powders, dissolved in a small cupful of cold water, to be given every quarter of an hour, until the excess of purging and vomiting subside and the pulse is clearly perceptible; from which time, extend the period between each dose, first to half an hour, then to an hour, and so on, till both pulse and breathing are vigorous. During the progress of this treatment, as much cold water or weak beef-tea may be taken as the patients desire; the more the better. Spirits and wine to be most particularly avoided.

Hot Saline Bath.

From seven to fourteen pounds of common salt, dissolved in a sufficient quantity of water to cover the whole body, and the patient must remain in from ten to twenty minutes, at a heat from 110 to 120 degrees; if necessary, the bath may be repeated every eight hours; after which, the patient must be kept in bed, and between blankets, with bottles of hot water to the feet and legs. A free admission of fresh air should be allowed into the apartment, and, if possible, to pass directly over the face of the patient; the body being kept as warm as possible.

The saline injection consists of the powder No. 3. dissolved in 32 ounces of water at the temperature of 100 to 110 degrees.

The following is a list of patients admitted into this hospital in the second or collapsed stage of cholera:—

Number of Patients.	Age.	Cured.	Died.
11	from 1 to 5 years.	5	6
7	5 — 10	4	3
13	10 — 20	12	1
26	20 — 30	16	10
44	30 — 40	25	19
31	40 — 50	16	15
24	50 — 60	8	16
17	60 — 70	5	12
11	70 — 80	2	9
Total 184		93	91

Cured.	Died.	Treatment of the above Number.
0	17	Either on their way to the hospital, or immediately after admission; the treatment previously, if any, not known; and no medicine could be swallowed during their short existence in this hospital.
5	13	By various plans of treatment, previously to the introduction of the saline medicine.
2	11	By various plans of treatment, succeeded by venous saline injections.
5	18	Under the saline remedies, but after stimulants, opium, and calomel, had been used in vain.
7	21	When brandy and laudanum had been freely given, previously to admission, or to the adoption of saline remedies.
0	4	Under the saline, in persons previously diseased.
74	7	Under the saline, and in persons where no other treatment had been adopted.

In addition to the above cases, 315 patients, labouring under the first stage of the disorder, have been treated by large doses of calomel, followed by purgatives of castor oil and tincture of rhubarb; twelve of which number ran into collapse and were treated by the saline remedies, but, eventually, only four died. It is right to remark, that the saline treatment, in this hospital, was first adopted by Mr. Whitmore, of Cold-Bath-Square, in a patient that was abandoned by myself, as a hopeless case—although this person recovered, and, by the like plan, many lives were prolonged, yet no uniform success ensued until the saline powders were faithfully administered every fifteen minutes, night and day, with an unlimited quantity of cold water. Hot saline baths were an important auxiliary, in fact, they never failed in relieving the cramps and exciting the extreme circulation, and thereby diminishing the lividity of the extremities. In every attack of the disease, that was not followed by purging and vomiting, all remedies were found perfectly useless, as all such individuals died, generally within six, never exceeding eight, hours, from the seizure, which, to me, affords ample illustration of the important effects of vomiting and purging in the collapsed stage of complaint, or even in the early stages, when the function of the liver is arrested. It is worthy of remark, that out of 13 patients, from the age of 10 to 20 years, only one was lost, and this died after a long struggle, having been injected 9 or 10 times with the saline fluid, rallying more or less after each addition to the venous fluid, the pulse being perceptible at the moment of death. In the 315 cases, there was not one who had bilious diarrhœa.

From the above facts, it is quite evident, that until the saline medicines, hot saline baths, and water without limitation, was steadily and faithfully administered, almost every case, in the second stage of disease, terminated fatally; while, on the other hand, nearly every patient who had not been previously treated by other remedies, but with whom the saline only had been pursued, almost every one survived, as the preceding report sets forth (that out of 81 cases in a state of collapse only 7 deaths). With the above facts before me, I must be not only blind to justice, but to all sense of honour and candour, were I not publicly to acknowledge, that until this treatment, suggested by Dr. Stevens, was forced upon my notice by stubborn facts, I not only treated it with disdain, but with determined opposition, yet I feel that I have been amply repaid, inasmuch as I have been taught a salutary lesson, never again to treat with indifference the suggestions of any man, without due reflection and careful investigation. Notwithstanding all the conflicting opinions that have appeared respecting Dr. Stevens's hypothesis, whether true or false, I care not, but I do feel, that to him alone is the profession and the public indebted, for the path that he has opened, the beacon that he has lighted, in the vast labyrinth of humoral diseases—for the new era that has commenced in both the pathological and therapeutical sciences — and for having thus cleared the threshold and opened the gates, from whence we view the distant light glimmering over the darkness of past ages, yet sufficiently bright to stimulate every scientific inquirer to a thorough cultivation of this unknown portion of human diseases.

WILLIAM MARSDEN,
Surgeon to the Free Hospital,
Greville Street.

2, Thavies-Inn, Oct. 10, 1832.

ANALYSES OF TWENTY-EIGHT REPORTS ON CHOLERA.

Besides the papers which we have given in the preceding pages, we have received numerous others, for which it is impossible to make room. We subjoin an analysis of the most important; with all of which, except those marked with an asterisk (*), we have been favoured by the Central Board of Health.

Dr. Wayte, of Lynn, Sept. 29.—Case of cholera with collapse, cured by cold water, in the manner of Dr. Shute.

Dr. Donnell, of Liverpool. Oct. 3.—In the first stage, thinks opium alone is required to stop the disease. In the second stage, laudanum to be combined with sugar of lead, in starch enemata, and repeated till purging be stopped; internally, 2 grains of calomel, and half a grain of opium, every hour. If case be severe, more calomel and less opium, repeated very frequently, as every five or ten minutes. Mustard poultice to stomach, if vomiting. Bleeding, if cramps, unless the patient be an old drunkard, or otherwise debilitated. "In 19 out of 20 cases this treatment succeeds."

In the third stage. Opium injurious: no plan yet tried of the least use.

Dr. Murphy, of Liverpool.—First stage to be treated boldly by means of calomel and opium. The violent vomiting continuing after the diarrhœa has ceased, best treated by prussic acid.

Second stage. If rice-water dejections, without vomiting, but with a natural skin as to heat, and a perceptible pulse—laudanum, 3i. to 3ij. instantly, enemata of sugar of lead and opium. If collapse just coming on, oil of turpentine in drachm doses every quarter of an hour. Brandy, Stevens's salines, calomel, bleeding, warm baths, all worse than useless.

Third stage. Has tried every remedy "that has been spoken of;" nothing particular to say in favour of any. Performed tracheotomy in one case, and inflated the lungs himself; thinks it prolonged life half an hour!

Mr. R. S. Dudley, Oct. 4, has given calomel with capsicum, of each gr. iij. every four hours, in the first stage, following the third pill with a dose of castor oil.

In the second stage he has given gr. v. of calomel every hour, or with longer intervals.

In the third stage he has abstained from stimulants, and latterly trusted to the cold water plan of Dr. Shute. Only three patients in collapse have been lost under this treatment: he does not state how many have recovered.

Mr. Greenhow (Oct. 1), our respected correspondent of Shields, continues decidedly against allowing the patients to gratify their desire for fluids; forbids stimulants; gives salt in gruel; sponges the skin with warm water; free admission of air; light bed-clothes; small doses of calomel and opium; effervescing draughts of carb. soda and tartaric acid; disapproves of emetics and enemata; thinks "we have often been induced to do too much."

Mr. Richard King, Tower, Oct. 3, has seen the disease chiefly at Darleston. At the onset of the disease, bleeding, sudorifics, gentle laxatives, antiphlogistic regimen. When a little farther advanced, and attended with vomiting and bilious purging, carbonates of ammonia and soda every hour, abstaining as much as possible from fluids. When purging has ceased to be bilious and fæculent, with cramps, &c. &c., mustard poultices to legs and stomach, followed by a blister, heat to the feet, scruple doses of calomel every hour till mouth be affected, water with a glass of brandy to the pint for constant drink. When there is total collapse, mustard emetic, scruple of calomel every hour, heat to feet, very cold water for drink, recumbent posture insisted on. The following remedies have been fairly tried, and found wanting: laudanum, cajeput oil, croton oil, oxymuriate of potass, heat to the surface (feet excepted), frictions, transfusion, and "quantities" of brandy.

Mr. J. Gardner, of Foley-place.—The successful treatment consisted in checking the most prominent symptom, and then proceeding on general principles.

If the spasms were very severe, and excited most attention; bleeding, pediluvium with mustard, &c. &c.

If the patient appeared exhausted, cold, pulseless, without much spasm or

pain, and without any commensurate evacuations; ammonia, frictions, nitrous acid and ether, brandy, &c. were all useful.

If the vomiting was most urgent, laudanum, ether, &c. until it was relieved.

If thirst, *cold water*, and this was in many cases extremely beneficial.

If pain in the stomach, mustard plasters and opium.

If diarrhœa the worst symptom, an astringent.

In many cases the exhaustion of the patient appeared to depend on the immense quantity of fluid evacuations from the bowels. In these cases a strong decoction of hæmatoxylon was the most decidedly useful.

In all cases calomel in large doses was given, to restore and evacuate the biliary secretions; but in several of the fatal cases, bilious evacuations preceded death.

68 cases of well-marked cholera treated: 18 dead, 50 recovered. Of the deaths, 13 took place in the collapse, 5 in the consecutive fever. Of those who died in the collapse not one came under treatment at the commencement of the attack.

---

* In the Institution to which we alluded in our No. for August 11, the surgeon to the Cholera Hospital (and we again omit the names, for the reasons formerly given) states, that in the premonitory symptoms small doses of calomel, combined with opium, followed up by cretaceous mixture, containing some warm aromatic (generally tinct. cardom. c., with tinct. opii, ♏ x. to each dose) proved very efficacious. Of 45 cases treated as above 43 perfectly recovered: the other two sunk into collapse, and died.

Eighteen were treated with the saline powders: 5 passed into collapse, and died; the others were long in recovering.

In the stage of collapse, where the pulse is not totally gone, mustard emetics, with muriate of soda, "repeated every half hour to about six doses," were beneficial. In complete collapse, nothing of marked service; perhaps an injection of three parts of warm water, with some brandy, as good as any thing. Cold water for drink affords relief: stimulants do harm.

---

*Mr. Lord, of Hampstead, under date Sept. 26, has forwarded to us a case in which a man, thirty years of age, recovered from the stage of collapse in cholera under the use of cold toast-water ad libitum.

---

* Mr. Howley, of Swansea, Sept. 24 and 25, relates a case in which a man, aged 55, recovered from collapse under the use of cold water. "The quantity of water drank in the first twelve hours was eight quarts: he slept three hours in the course of the night, and drank seven pints of water, and four more from 8 till 11 A.M. on Monday." He was taken ill on Sunday, and was attended by Mr. Howley and Mr. Edwards.

---

* Mr. Littleton, of Swansea, in a letter dated Sept. 12, states, as the result of his experience (having seen above fifty cases), that the most efficient treatment of cholera, when distinctly marked, is the exhibition of "three or four grains of tartarized antimony every twelve minutes," till full vomiting is produced, following this up in two or three hours with thirty or forty grains of calomel.

---

* Mr. Rose, of Swaffham, Norfolk, recommends nitrate of silver, one-eighth to one-fourth of a grain, in four pills; one to be taken every half hour. Mr. Rose has never treated a case of the epidemic.

---

* Mr. W. de Garrett, of Edinburgh, suggests *a combination* of the various active remedies which have been recommended, and enumerates particularly—Latta's injections, Stevens's powders, tight bandaging, croton oil, and cold water. He gives a case in illustration, in which, however, calomel and opium appear to have been the chief means employed: the patient recovered.

Mr. J. Burrows, Stonehouse.—All the cases except five already in the state of complete collapse: 67 treated, 32 dead, 35 recovered. Principal remedies, about gr. ii. of calomel every quarter of an hour, followed by a tablespoonful of camphor mixture, with spirit. ammon. aromat., mustard cataplasms, terebinthinate enemata, with laudanum. After some improvement, blue pill, sudorifics (liq. acet. ammoniæ, liq. antim. tart.), laxatives, effervescing draughts.

Mr. Maurice, Chairman of the Board of Health, same place, states that no case of cholera, even of the slightest

kind, occurred in the poorhouse, containing eighty-six inmates, though the disease raged round them, and eighty deaths took place within a hundred yards of the building. Their diet, &c. was regulated, "and every precaution taken to prevent communication with the town."

Mr. Woodman, St. Thomas's, near Exeter, (Oct. 5, 1832,) has treated 182 cases, whereof 21 died and 161 recovered: the majority (about 150) seen previous to collapse: of these only 6 died. The treatment adopted in the early stage was b'eeding to six or twelve ounces: calomel one scruple, with opium grains iss., when purging was profuse. When vomiting is urgent, saline effervescing draughts; calomel repeated till salivation be induced: if collapse threaten, a powerful stimulus.

In collapse, bleeding tried in six cases; seemed to hasten death. Trusts chiefly to boiling turpentine, applied externally by wrapping linen cloths, which have been dipped into it, "securely" round the legs and arms; the same application to pit of stomach; "does not remember a single case of troublesome vesication. Calomel continued (and mercurial frictions adopted when reaction has occurred); spirit ammon. aromat. freely.

In one case (a child three years old) cold water has just been used with advantage, turpentine being applied to extremities, and calomel given freely.

Dr. Vallange and Mr. Anderson, of Portobello, (Oct. 2, 1832.)—In the stage of bilious diarrhœa, castor oil, with thirty drops of laudanum, and followed by calomel or blue pill, proved successful in every case.

When rice-water dejections, &c. came on, the stimulants fairly tried and entirely failed. Plan afterwards adopted consisted in large doses of calomel and colocynth, opium, hyoscyamus, venesection "in every possible case," large enemata of hot water, external stimulants. In two cases tried the inhalation of nitrous oxide; think very favourably of it, but had not the means of trying it fairly. Cases treated, 40; died, 24; recovered, 16.

Dr. Stephen, of Portobello, (Sept. 28, 1832.)—Practised at Musselburgh during the epidemic. In the first stage, a bleeding of 10 to 12 ounces, where age and constitution admitted of it; this followed by 25 to 35 drops of laudanum, and subsequently by castor oil, or compound powder or tincture of rhubarb. In second stage almost invariably fatal. Saw most benefit from port-wine injections, with half a drachm of sulphate of quina, of starch with opium, or kino or catechu, with small and oft repeated doses of anodynes by the mouth, succeeded by wine and water where the stomach had become less irritable. In the third stage has not found any thing of much use.

Mr. Banner, of Liverpool, (Sept. 17, 1832) has treated 186 cases; viz. 72 in the first stage, 91 in the second, and 23 in the third: out of these cases 12 have died.

First object, to allay the irritability of the stomach, and get the system under mercury. To effect this has bled to syncope, by which the vomiting and cramps, and not unfrequently the purging also, have been stayed; then calomel, grs. iij. with $\frac{1}{4}$ grain of opium, every three hours, till symptoms subsided, which has usually been after the third or fourth dose. In 14 or 16 hours after the evacuations have ceased, an ounce of castor oil. In only one instance has the first stage under this treatment passed into the second. In second stage, bleeding to syncope, but here not so effectual as in first stage. Calomel found to be best retained in powder, viz. cal. gr. iij., with an equal quantity of sugar, and $\frac{1}{4}$ grain of opium. Perseveres with the calomel till mouth be affected. Mustard poultice to stomach; port wine, half an ounce, with carbon. of soda, half a drachm, every half hour. Warmth to feet very important. In third stage bleeding "undoubtedly injurious:" trusts to calomel and opium, in small doses, every half hour: port wine in large quantities; mustard poultices, frictions, &c.

Drs. Squires and Lane, Messrs. Bevan and Turner, of Liverpool, (Sept. 24, 1832.)—In first stage, bleeding, calomel not exceeding grs. v., and opium not exceeding gr. iss. If pain about the chest, mustard cataplasm to stomach. In a few hours a moderate dose of castor oil, with a few drops of laudanum in peppermint water. Of 200 persons thus treated in the Refuge House (*i. e.* for

premonitory symptoms) only 16 required to be taken to the hospital, of whom 4 died, so that there were 196 cures, not followed by fever.

In the second stage, if pain or uneasiness in chest, bleeding, without reference to state of pulse. If pulse did not rally under it, flow was stopped, to prevent fatal collapse. Small doses of calomel, minute portions of opium, frequently repeated. No patient lost when the slightest ptyalism was produced. Mustard cataplasms to the abdomen. If purging excessive, enemata of starch and opium. Vomiting and thirst combated by saline effervescing draughts in small quantity. *Hot* tea; stimulating liniments and frictions externally; heat to the extremities.

In third stage, bleeding to be adopted with extreme caution. Most useful remedies are, calomel and opium in *small* doses; small quantities of camphor in a very moderate portion of brandy; free use of stimulants decidedly injurious in this and every stage of the disease; external irritants and heat to surface; hot drinks. Have tried "every mode of treatment, from the saline remedies to cold water *ad libitum*, and have been compelled to discard them."

Mr. Kelly, of Liverpool, (Sept. 20, 1832.)—In first and second stages, injections of a drachm and a half of laudanum, with grs. viij. of sugar of lead, and tincture of catechu one ounce, in eight ounces of starch mixture, repeated every two or three hours.

In the collapse trusts to mild stimulating "*diet*," and enemata containing astringents. Cannot speak so favourably of calomel as others do. Thinks saline injection deserves further trial; has succeeded with it in three cases out of twelve.

Messrs. Wightman and Clark, of Carwood, near Selby, (Oct. 5, 1832.)—First stage, Dover's powder in large doses, with absorbents; astringents, and anodyne injections.

Second stage, an emetic, sudorifics and injections as above, calomel in small doses, with Creta peppermint, every ten or fifteen minutes, soda water, effervescing draughts, sinapisms, heat to feet, &c.

Third stage, powerful sudorifics, calomel and chalk, sulphate of quina, musk, camphor in large doses: other remedies as above.

Cases treated, 87; died, 17; recovered, 70.

Mr. J. Windsor, of Liverpool, (9mo. 17th) in the first stage, has found chalk mixture, or an astringent aromatic mixture, with a portion of opium, to have been efficient "without exception." When rice-water evacuations have come on, he depends on calomel and opium, gr. iii. to iv. of the former, and gr. ss. of the latter, every half hour: "when the least ptyalism was produced, the patient was safe." In collapse, has tried ammonia, soda, camphor, opium, &c. but with little advantage. Has treated about 120 cases: 6 died during the rice-water evacuations, 10 in collapse; 104 recovered.

Mr. Gaselee, of Southwark, (Sept. 26, 1832.)—Mere bilious diarrhœa to be met by ordinary treatment; but where the purging is *very* profuse, and more particularly if it have passed into the form of rice-water dejections, the object is to stop all the discharges, for which purpose opium is his "sheet anchor;" but this, to be efficient, must be given largely, and repeated according to the recurrence of the alvine discharges. The great principle of this gentleman's treatment is arresting the evacuations, and when this is done he is in no hurry to give aperients; thinks the third day early enough. Stimuli of the spirituous volatile character are also exhibited when the patient is depressed. Smaller doses of opium to be continued, and, if required to control the discharge, also enemata with laudanum.

In collapse, approves of a warm room, hot fomentations, small but repeated doses of ammonia, moderate quantities of brandy, port wine, or gin and water, small opiate enemata, water or soda-water (but not largely) for beverage. Does not believe that any medicines act specifically. Concludes with these words: "It will thus be evident that in the treatment of collapse I cannot call myself successful: in the preceding stages nobody ought to be otherwise."

Dr. Branson, of Doncaster, (Oct. 4. 1832) for himself, and all the professional members of the Board of Health. Up to the 9th of June, 14 cases, 9 deaths; from 9th of June to Sept. 3d, 98 cases, 17 deaths, 81 recoveries. The treatment during the former period consisted of stimulants and opiates; afterwards

calomel was chiefly trusted to, but preceded by an emetic and bleeding. The mode of proceeding is thus described:—

"There was scarcely a case in which the rice-water evacuations were not observed, and the practice which was found to be the most successful was, to administer a mustard emetic, and at the same moment to bleed. The operation of the emetic was almost instantaneous, and promoted the flow of blood from the vein, which, in some cases, might not else have been obtained. In ten minutes after the emetic, ten grains of calomel were given, and if the cramps were severe, two grains of opium at the same time; and in fifteen minutes more, five grains of calomel alone, and so repeated every fifteen minutes until the colour and quality of the intestinal ejections were altered, and they had assumed a dark brown, or rather a dark green colour, resembling chopped spinach; after which the calomel was discontinued, and the only medicines required were small doses of castor oil, so as to secure the daily emptying of the bowels, and occasionally effervescing draughts, to allay the sickness.

"It was early observed that repeated doses of opium produced symptoms of cerebral congestion, and afterwards a most obstinate and irrepressible nausea, for which reasons we rarely repeated its use.

"The form in which calomel was given, namely, in powder thrown on the tongue, and washed down with cold water, secured its retention, it scarcely ever having been rejected by the stomach. The quantities of calomel thus given within 24 hours, varied from 60 to 255 grains; and the present state of perfect health of the subjects of this practice, proves that the system has sustained no injury from the large quantities of mercury taken."

Bland fluid nourishment. The horizontal posture strictly enforced.

Mr. Wiggins, of Wallington, Oxon, (Oct. 8, 1832.)—In bilious diarrhœa, calomel in rather large doses, rhubarb, cordial and saline stimulants. In rice-water evacuations, if much sickness, salines, with carbonate of ammonia in excess, and tinct. of calumba, with four grains of calomel every hour. If diarrhœa, without much vomiting, calomel as above, with a grain of opium, weak brandy and water. In collapse, carbonate of ammonia, in doses of 15 or 20 grains, every half hour, the best stimulant. As soon as warmth begins to return, an ounce of brandy and water (strong) every quarter of an hour. Thinks well of "a spirit bath," and ill of warm water bath. Has seen much advantage from camphor and opium—one grain of the latter and four of the former.

Mr. Thomas, of Liverpool, under date Sept. 17, says, in answer to *Prop.* 1, when the choleroid pestilence is epidemic in the neighbourhood, I consider the bilious diarrhœa a premonitory symptom. I always bleed if the pulse will bear it; the blood taken exhibits two streams combined in one—a purple and a scarlet stream. I allow the blood to flow until the whole becomes of an uniform standard colour. The pulse, in the commencement, is usually broad and soft; at the termination of the operation it is firmer and more contracted. I administer calomel and opium at the commencement—one grain of the latter to four of the former, every hour, until the motions become more consistent. This practice I occasionally vary: if the motions be watery and yellow, with patches of mucus floating in them, I administer a table-spoonful of the following mixture every half-hour:—

℞ Misturæ Cretæ, ℥vij.; Confection. Opiat. ℥iss.; Tinct. Cin. Co. ℥j. M.

I generally find the diarrhœa checked after the third or fourth dose. I also use injections of catechu and opium into the rectum; and if much tenesmus be present, enemata of mucilag. amyli cum opio, instead of the catechu. I have also, after the liquid bilious diarrhœa is checked, prescribed with advantage the hydrargyrum c. creta, combined with the compound powder of ipecacuanha, every hour. If these powders do not move the bowels, I prescribe a pill composed of four grains of the submurias hydr. and two grains of socotrine aloes, which generally produces solid motions. The castor-oil is afterwards to be employed, to regulate the bowels.

Prop. 2.—I have bled in this case without advantage, and therefore deprecate venesection. I prescribe the chalk mixture, with carbonate of ammonia and tincture of catechu, and rapidly repeated doses of the hydrargyrum c. creta, or calomel and opium, every half hour (2 grs. hyd. to $\frac{1}{6}$ gr. of opium).

The grand object which I have now in view is to get the system under the influence of mercury as rapidly as possible. I allow brandy in moderate doses, (a table-spoonful every half-hour,) or port-wine negus well spiced. I enjoin counter-irritation over the abdomen with mustard plaisters; also injections into the rectum of catechu, with a little laudanum. In general I avoid opium as much as possible in this stage, lest the nervous system should become narcotized.

Prop. 3.—In this stage I consider that there are two indications to be fulfilled: 1st, to arouse the functions of the nervous system, more especially those of the sympathetic ganglia; 2dly, to furnish a *basis* for the immediate elaboration of fresh blood. The best stimulus I consider to be mercury. I have employed the oxymuriate in desperate cases (¼ grain every half hour); in conjunction with which, frictions with mercurial ointment have been employed. The spinal column must be stimulated by plaisters of mustard from the nape of the neck to the lumbar vertebræ. If the mustard produces no effect in the course of an hour (which is sometimes the case), frictions with the pure water of ammonia and nitric acid, must be used, by small dossils of lint dipped in these caustic liquids. I have found the nitric acid applied with a feather, in the malignant collapse, merely to stain the skin, and to produce scarcely any sensation. The skin will soon be destroyed if the friction be used, and then counter-irritation will be established. I have prescribed the oleum terebinthinæ (a drachm or two) every half-hour, with mucilage, in some cases with evident advantage, in others without success. In some cases I have found the phosphoretted ether, with tinctures of cantharides and cinnamon, useful. Mustard cataplasms may be applied over the abdomen, as in the case Prop. No. 2.

The second indication I attempt to fulfil by the frequent administration of spoonfuls of mutton-broth, spiced. It should also be administered by the rectum. I continue the stimuli until I find the tunica conjunctiva is becoming vascular. I make a point of frequently depressing the lower eye-lid; and if I perceive an artery starting up immediately perpendicular to the pupil, I know that it will quickly shoot out ramifications over the sclerotica: this I consider a signal for the withdrawal of all spirituous stimuli. If the patient be not mercurialized before this (if he escape out of the collapse), he will probably be cut off by inflammation of the brain and effusion, when the fever of the pestilence unmasks itself. I have either tried, or witnessed the trial, of the following systems:—Dr. Stevens's saline plan; Dr. Hardwicke Shute's cold water plan; the injections of saline solutions into the veins (which I recommended to the Central Board as a plausible experiment on the 15th February last); and the result of my experience and observation is, that they are not attended with sufficient general success to sanction a deviation from established practice. It behoves me, however, to state that I have seen cases of malignant collapse, in which I am persuaded the patients were cadaverized *ab initio*. In these cases, the functions of the sympathetic were absolutely annihilated.

Such is the general plan of my treatment of this pestilential fever. A more particular detail of the modifications of treatment adopted in all the complex varieties and intricate phenomena of the disease, would require a much greater space than it would be proper at present to occupy. Such modifications of administration must depend upon the mode of the development of the disease, and the view which individual practitioners may take of such symptomatic exemplifications.

For the following sensible letter from Mr. Barnett, addressed to the Secretary of the Central Board of Health, we are happy to find we can make room:—

Sir,—The unimportance of any communication which I could make, towards the improvement of the treatment of malignant cholera, has been the cause of my not attending to your request before; but as the disease has very much decreased in this neighbourhood, and the opportunity of observation gone by, I think it proper to make known to you the result of my observation in upwards of 200 cases.

That the diarrhœa, while bilious, was, without exception, under the influence of those remedies commonly used for diarrhœa occurring from other circumstances; viz. opium, catechu, chalk, cinnamon powder, logwood, &c. &c. And when, from some particular consti-

tutional or other causes, the mucous membrane of the stomach and bowels was irritated or inflamed, blue pill, combined with opium and ipecacuanha powder, blisters, mustard poultice, &c. &c.

The collapse appears to me to be the consequence of the rice-water dejections, therefore the commencement of the one is the necessary result of the other, to a greater or less degree, according to the loss from the circulation*. In this stage of the disease, I believe, from the very commencement, remedies have little effect. I have seen an equal number recover under every kind of treatment, except the direct stimulating, such as brandy, &c. under which I have seen very few recover. But, at the same time, I think the collapse has been, in many instances, accelerated by every description of treatment, when commenced in the second or third hour of rice-water dejections; *e. g.* calomel, saline, &c. &c. but particularly from large doses of opium.

I believe, after the collapse has somewhat progressed, the system is insusceptible of remedy (except the injection into the veins). My reason for coming to this conclusion is, that I have, in many instances, rubbed 12 ounces of strong mercurial ointment combined with camphor, and in other cases with mustard powder, over the whole surface of the body in the space of 40 hours, and given, at the same time, 5 grains of calomel every half hour, without the least soreness of the mouth or any other sensible effect.—The injection into the veins has an evident effect on the pulse, but is not lasting.—I have not seen more recoveries by injection than other means. But, of this remedy, I think we want more practice to know how to use it to advantage.—I am by no means an advocate for bleeding at this period of the disease.—Though I am of an opinion that mercury has no effect over the collapse, still, when the system struggles through, and mercury has been and continued to be used, the third or fever stage is more likely to be recovered from; but, merely because this powerful therapeutic agent has been used, in the earliest susceptible state of the constitution, to medicinal influence. When the disease has passed through the collapse, and the system perfectly reacts, it is again subject to curative means; and those remedies, which are generally used for congestive fever of a typhoid kind, become beneficial: mercurial inunction, and calomel in small and repeated doses, until the mouth becomes affected, should be a principal feature in the treatment of this stage; ipecacuanha, saline medicines in a state of effervescence, &c., also mild purgatives of rhubarb or castor oil, will be occasionally necessary. In consequence of the unequal state of the circulation, and the change which the blood sustains in course of the collapse, also the consecutive derangement which the nervous system suffers from such change, you will have certain organs much congested, (the brain, liver, lungs, and bowels,) therefore it is, in most cases, necessary to have recourse to local, and, in some instances, *careful* general bleeding. I say careful, because my experience does not warrant that copious bleeding which, I know, several advocate. Local counter-irritants, mustard poultices, blisters, &c. are of course necessary: and, indeed, if this stage is treated upon the common principle of congested fever, observing the beneficial effect of slight ptyalism, it will be generally recovered from. Stimulants are commonly very injurious in this stage. As my object is merely to lay before you, in a summary manner, a general outline of the conclusions of my experience in this disease, and as the opportunity is over of my making further intended trials of the injection into the veins, altered in its modus operandi, and combined with galvanic or electrical influence, I must quit the subject by saying, that we have certain curative means for the præmonitory stage; that the means necessary for the recovery from the stage of rice-water dejection, and consequent collapse, we are as ignorant of as we were at the first appearance of this epidemic; but the third, or fever stage, is under the influence of therapeutic means.

I am, your most obedient, &c.

T. W. Barnett, Surgeon.

Limehouse, Oct. 4, 1832.

* I do not wish to be understood to mean, that collapse cannot take place without dejections, because, I believe, the serum of the blood may pass into the bowels, and produce the same effect as if it appeared in the form of dejection.

BILLS OF MORTALITY.

To the Editor of the Medical Gazette.

Sir,

The interesting communication from Mr. Babington, published in your last number, must have satisfied your readers of the advantages which statistical medicine may reap from a well-organized system of parochial registers. The Worshipful Company of Parish Clerks, by whom the London bills of mortality are prepared, are fully sensible of the defects pointed out by Mr. Babington, and for many years past have been anxious to rectify them by means of a parliamentary enactment. A bill "for better regulating the returns of christenings, burials, and marriages, in London," was accordingly brought forward last session of parliament; but owing, I believe, to the all-engrossing reform question, was ultimately withdrawn. The bill will doubtless be again brought forward, and, I trust, with better success.

One great object of the measure was to compel a return from the lazy and refractory parishes. Mr. Babington deplores the absence of all returns from *certain* parishes, but he omits to state that the great defaulter is the parish of St. George, Hanover-Square. I have heard several explanations given of this obduracy on the part of St. George's parish, one of which ascribes it to a belief of the uselessness of these weekly registers. I cannot but hope that now, when the value of the bills of mortality is acknowledged in one of the best periodicals of the day, and their defects are regretted by one of the most enlightened surgeons of St. George's Hospital, the interdict will be taken off, and the mortality in this populous and important parish no longer left to be guessed at. It is, I presume, competent to the vestry of the parish to direct their clerk to make the requisite returns.

I am, sir,
Your obedient servant,
"Old Mortality."

Gravesend, October 9, 1832.

PROTRACTED GESTATION.

To the Editor of the Medical Gazette.

Sir,

I beg leave to submit the following case to the consideration of your correspondent, Mr. Morrison:—

A few years ago an action was brought, at Lancaster, by —— Anderton, against John Whittaker, "to recover compensation in damages for the injury caused to the plaintiff, in consequence of the seduction of his daughter, which had deprived him of her services."

Margaret Anderton being sworn, and examined by Mr. J. Williams, stated, "it was on the 8th of January that I had the intimacy with the defendant, but never had any with him before or since. The child was born on the 18th of October."

On her cross-examination she said, "the 8th of January was a Sunday. I don't know where the defendant had been spending the day, but he came to our house in the evening, and staid till ten or eleven at night: my misfortune happened about eight o'clock. The defendant and I, and Betsy [her sister], were in the kitchen, and my father and mother in bed. I never walked out with him at night."

Re-examined.—"My sister Betsy was in the room. . . . . Defendant requested Betsy to leave the room, as he wanted to have some conversation with me. We were never left alone before, as Betsy generally sat up with us."

"Betsy Anderton, the sister of the last witness, confirmed her testimony in those parts in which her name was mentioned."

"The Jury having consulted a few seconds, returned a verdict for the Plaintiff—Damages, 50*l.*; costs, 40*s.*"

From the 8th of January to the 18th of October inclusive, makes 284 days, or rather the child was born on the 284th day of pregnancy; but no observation appears to have been made by the counsel for the defendant (Mr. Knowles) on this protracted gestation; he did not attempt to disprove the dates, but rested satisfied with what bears upon the face of it, a very unusual length of time for pregnancy, particularly a first pregnancy, to reach. Annotator.

Sept. 17, 1832.

MEDICAL GAZETTE.

Saturday, October 13, 1832.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."
CICERO.

HYPOCRITICAL ADDRESSES TO STUDENTS.

We promised, in pursuance of our purpose of noticing those points in our medical institutions which we hold to be susceptible of improvement, to take up the subject of medical education specially, and to discuss its present state, extenuating nothing, nor becoming the apologists of any party—freely and independently censuring, where censure is deserved—approving, where we deem approbation due—counselling and exhorting, where we think any good, however remotely, can be effected by such means. That promise we mean presently to perform. But it ought to be premised, that it is by no means our intention to dogmatize, or hold forth *ex cathedra*, on the subject. We trust to be able to execute the task which we have set ourselves, in an impartial but unassuming manner—so as to engage the attention of all who are in any wise connected with the profession—from the presidents of the corporations, and the corporations *en masse* and in detail, down to the students who are enrolling themselves as aspirants to professional standing. We are anxious that this should be understood *in limine*, that the students may be distinctly apprised that they are invited to our amicable parlance, and may know, that never for a moment do we intend to lose sight of their interests. It would be strange, indeed, if such a topic as that of education should be discussed, without the proximate material (to use a phrase of the logicians) occupying even the primary rank—having a front row, at least, allotted to them among the crowded benches of the arena. The students have the more need to be advertised of this, as there are those abroad, who, we are grieved and indignant to see, are not unwilling to practise on their inexperience; they have it dinned into their ears that they (the poor simple students) come to town as sheep to the slaughter—that the schools of the metropolis are the shops of nefarious sharpers—that there are snares set for the incautious in all directions—and that they must beware of what they do. There is an air of kind consideration for the pupils' persons and property in all this, that is very *imposing:* the solicitude for regulating the management of their purses is, assuredly, very conspicuous; and the suggestions vouchsafed for the expenditure of their finances at the best market, are of the friendliest and most considerate description. The pupils, of course, are full of gratitude for this fatherly kindness and regard, and are all of them possessed of the precepts, and imbued with the practical information, of the benevolent guide who so fortunately came in their way on their arrival in town—who saved them from precipitancy, and possibly from ruin.

But simple, indeed, and inexperienced, must be the youthful mind that is caught by such palpable chicane. Have any of the merest tyros who are now attending the metropolitan schools, come to town so green as not to be proof against such manifest imposition? Which of them has not perused the "Dangers of the Metropolis?"—or has not heard of the feats of the London ring-droppers?—or read the History of Jonathan Wild? Those who have, are safe enough—those who have not, had better be on their guard: and when they find themselves fallen into company with one who gratuitously tenders them his services,—puts upon them his intrusive advice, and bids them take care of their pockets—who insinuates,

nay, who does not hesitate to declare, that he holds all lecturers to be *roués* and all the schools to be traps—who exhorts them to sit in judgment on their teachers both before and after selection—who preaches distrust and disaffection, and the right—the expediency—of open resistance; yet, with curious subtlety, advises the student "not to *incur the risk* of injuring his future reputation by acquiring a *pernicious notoriety, founded on a charge of a turbulent disposition*;" —when they find all these properties prominently possessed by an individual, or individuals, soliciting their better acquaintance, let them look well to it: they will soon be sensible of the necessity of inquiring who it is that gives this unsought-for advice; and if, upon inquiry, they find a contrast between the character of the giver and some part of his admonitions, with an ill-disguised hostility to good order pervading the whole (and a little insight into the doings of the Archimago they have to deal with will be sufficient to convince them of this)—once more we say, let them look to it, and in time be warned—of their warner.

It is a painful duty—but nevertheless a needful and imperative one in the present case—to excite suspicion in the minds of the young and inexperienced; but where there is a poison there ought to be an antidote; and when suspicions of the worst and basest description are disseminated to the prejudice of gentlemen of high attainments and moral character—men who have been mainly instrumental in making the profession what it is—the guardians of its well-being, and the fosterers of those who are to be entrusted with a similar responsibility hereafter—it is full time that counter-suspicions should be suggested, though they extend no farther than to the inquiry, who are they that presume to do such things? Should they turn out to be the common slanderer, the noted disturber, and the oft-convicted libeller—then the inquirers shall have profited by their second thoughts, and the suspicions raised in their minds shall have been productive of positive good. It is with this view simply—a justifiable and proper one, as all our reasonable readers must admit—that we have ventured to touch upon such a subject; for who is there that knows any thing of the party to which we allude—so notorious for scattering tares wherever they may chance to find root—that does not feel indignant in observing hypocritical addresses to pupils, on the commencement of their career, emanating from such a quarter; addresses which, under the mask of advice and caution, inculcate principles of the most inflammatory and dangerous tendency?

We will be bold to say, that never was a more audacious calumny than that which charges sordidness and insufficiency on the London teachers—never a more decided libel upon the whole profession: for where, if not here, in this metropolis, may a competent body, for educational purposes, on the most extensive scale, be found?—where is there collected together, and occupied in the business of teaching, such an assemblage of celebrated men? And if *they* be the mean, sordid creatures that jaundiced, self-constituted censors, would have the world believe them to be, adieu to the honour—the grace—the respectability—the common decency of the whole profession! Better the students should give up all notion of connecting themselves with it at all!—It is enough to have touched upon these false and audacious charges: the very noticing of them is a necessity which every well-wisher of medicine must regret—to dwell upon them would be to give them an importance which they merit not: we turn to a subject more welcome and more suited to our pen—some general remarks upon the London School.

We speak of the London School as *one:* for we have long been in the habit of contemplating it in this point of view. We look upon the numerous corps of teachers of science, both medical and general, within the walls of this vast metropolis as constituting a University in the largest sense of the word; and upon the several schools, properly so called, as so many departments co-operating, or which ought to co-operate, with one general design. That London is at present virtually a University, containing many Colleges, in which every branch of human knowledge is taught, and by many of the ablest teachers that the empire can produce, is a fact beyond a question. There is no essential requisite which it does not possess—no advantage, desiderated in the ancient seats, which it does not fully enjoy. The only ground of reasonable apprehension, in regard to this our national establishment, is, lest the spirit of ultra-rivalry, which we perceive is at work, be allowed to go too far: for we can scarcely avoid observing a number of petty states, each contending for its own independent pre-eminence, and a few of the larger ones aiming at the erection of *imperia in imperio.* But, perhaps, while there is much to apprehend in such a system, there may also be something in it not undeserving of praise. If rivalry be confined to a contest for pre-eminence on fair and liberal grounds, without an attempt to palm upon the student names for things, there is in London, we will venture to say, as much material for scientific produce, and, with unanimity, there might be as near an approach to excellence, in the workings of the various rival establishments which it contains, as the nature of imperfectly regulated human institutions will admit.

We will resume this subject, if possible, in our next.

EXHALATIONS FROM FILTH.

A SMART discussion recently took place in the Academie de Médecine on this subject, originating in the following circumstance:—When the cholera appeared at Blois, a resident physician saw with alarm that the public workmen were employed in unpaving the streets, for the purpose of repair. He apprehended that the emanations which would arise, would prove fatal to all who were disposed to be affected with cholera. He accordingly wrote to the Préfect of the Loir-et-Cher, who sent in his letter to the Minister, and the latter applied to the Academie for their opinion on the subject. M. Double was entrusted with the drawing up of a report, of which the conclusions were these:—"that the exhalations of putrid animal matter are by no means so dangerous as have been supposed; and that the disturbing of the streets or soil for any public or necessary purpose need not excite any degree of alarm." M. Dalmas made an objection to the wording of the first inference, inasmuch as it implied *some* danger, whereas from the experiments of M. Duchâtelet we should conclude that there was none whatever. M. Piorry suggested that putrid animal matter injected into the veins produced very fatal results. But M. Marc and M. Double defended the report; which was eventually adopted.

INCREASE OF CHOLERA IN SCOTLAND.

WE are sorry to state that the cholera has considerably increased at Dumfries, Edinburgh, and some other parts of Scotland, within the last fortnight. We understand that, in some of those places, this augmented activity came on immediately after the discontinuance of gratuitous supplies of food to the poor had taken place,—a measure which the exhaustion of all the funds which could be received by charitable contribution, as well as of that received by the authority of the Privy Council, unfortunately render unavoidable.

SPANISH ANTI-CHOLERA MEASURES.

EVERY traveller, from an infected district, is subjected to the performance of quarantine at Perpignan or Bayonne; and, if he enters Spain without having gone through the formality, he is subject

to be punished with death, his apparel burnt, and his goods seized. The same punishment is extended to those who may receive him. Such is the ordonnance of the Captain General of Barcelona — a pretty strong measure, it must be confessed.

ITALIAN PHYSICIANS CONTAGIONISTS.

Several physicians, sent from Italy to Paris to study the cholera, have, in the account published on their return, declared their conviction, that the disease in that capital was contagious. It is remarkable that while the practitioners residing in towns where cholera prevails have often been non-contagionists, an opposite view has almost invariably been taken by those having no local interests, but sent from a distance to watch the disease, for the guidance of those in places which it had not yet reached.

NEW ANALYSIS OF THE BLOOD IN CHOLERA.

By M. Lecanu.

The first remarkable circumstance attending the blood in this disorder, is the singularly augmented proportion of its fixed matter. In three experiments, which I think may be depended on, I found the mean proportion of fixed matter to amount to 37 per cent., leaving 63 for the water*. But it is known that the blood in health contains 79.1 per cent. of water, the maximum being 80.1, and the minimum 78.1; whence the blood of cholera patients must be understood to contain more than twice as much fixed matter as the blood of people in health.

* In one experiment I found —

Water	66
Fixed Matter	34
	100

In another:

Water	74.9
Fixed matter	25.1
	100.0

And in a third:

Water	48
Fixed matter	52
	100

Mean quantities:—

Water	63
Fixed matter	37
	100

With regard to the fibrine, albumen, and colouring matter, I have nothing particular to observe, except, indeed, hat in the cases which I examined, the colouring matter appeared to have undergone a modification similar to that which arterial blood exhibits on being changed to venous, though my re-agents have not been successful in determining its nature.

I have experienced the greatest difficulty—amounting indeed to a positive obstacle—in attempting the quantitative analysis of the blood in cholera, owing to the impracticeability of separating the serum. I have reason, however, to dissent from the opinion of M. Hermann, of Moscow, whilst I accord with that of M. Rayer, that cholera blood presents not the slightest trace of acid properties. Whether I coagulated it with alcohol or by heat, I could not obtain, above once in five trials, a liquor that perceptibly reddened some turnsol paper; and this delicate change of colour may have been altogether owing to commencing decomposition, for the alcohol which I used to coagulate a part of the same blood, remained neuter with coloured reagents.

But on the other hand I have always been able to trace in cholera a sensible diminution of the alkaline carbonate contained in healthy blood.

I am inclined to believe that the remarkable augmentation of fixed matter above-mentioned, is not owing to the formation of a greater proportion of globules, but to the withdrawal of a quantity of serum, more or less considerable. This opinion I form from the quantity of carbonate of soda, albumen, and that peculiar extractive matter which has been compared to osmazome, ordinarily found in the stools of cholera patients previous to their death. I am aware that some chemists have found the stools acid, and some alkaline; but this, I think, has been owing to the time chosen for making their experiments. For example, in the case of the Sieur Cartier, one of the first victims to cholera in Paris, the stools passed the night before and the morning of his death were distinctly alkaline, whilst the matter found in the large intestines, at the autopsy, was strongly acid.

The white and fibrinous looking matter found in the stools, and which has caused them so often to be compared to rice-water, seem to me to present more

of a mucous than a fibrinous character: there is besides no deficiency of fibrine found in the blood which has been analysed.

Paris, Sept. 20, 1832.

INSOMNOLENCE CURED BY SULPHATE OF QUINA.

M. BARBIER, of the Hôtel Dieu, Amiens, relates the following case:—A man, aged 42, had cholera, from which he recovered; all the functions were restored, except that his sleep was destroyed; scarcely had he an hour's rest altogether in the course of each night; laudanum and other soporifics were exhibited without effect. M. Barbier found, on examination, that every evening he had a nervous "agitation," which lasted all night, accompanied by some pain in the head and limbs. Looking to the *periodicity* of the affection, M. Barbier ordered six grains of sulphate of quina every night. It was given two nights; he slept well; it was then omitted; he had no rest. The medicine was again renewed, and continued, with the effect of permanently procuring six or seven hours of sound sleep.—*Gazette Médicale.*

MUSK IN FLOODING.

In uterine hæmorrhage, particularly after labour which has been too precipitate, Dr. Hauff states that he has found musk, in doses of eight or ten grains every quarter of an hour or every half hour, to be an excellent remedy.—*Medizinisches Conversations-Blatt, No.* 3.

CLINICAL REPORTS.

OBSERVATIONS ON CLUB-FEET.

By M. DUPUYTREN.

M. DUPUYTREN lately exhibited at his clinical lecture an infant born in the Hôtel Dieu, having two strongly marked club feet. The learned surgeon took the opportunity of making the observations which follow:—

Club-foot is for the most part a congenital deformity, in which the foot is turned very much inwards, the sole being nearly perpendicular, and the external edge looking down, so that the individual rests upon it, or, when the deformity is very great, even on the outer ankle. At the same time, the cavity of the sole of the foot appears to be augmented. All these external phenomena have been well described by Scarpa and others. Scarpa and M. Cruveilhier have also occupied themselves with the interior appearances displayed by dissection, but none of them have sufficiently dwelt on the most important results of the club-foot—namely, the diminished nourishment and consequent atrophy of the limb.

Congenital club-foot is either limited to one or involves both members. In the former case, if the infant be examined very soon after its birth, the deformed foot is found to be rather smaller than the other, but the legs are of equal length. M. Dupuytren has had numerous opportunities of satisfying himself on this point. When both feet are affected, they are in general equal in point of development. This kind of premature atrophy, the unknown cause of which is probably connected with that of the deformity itself, produces as a consequence a secondary wasting, which extends to the entire limb, and the source of which may be better explained. In fact, the infant, from the day he begins to walk, constantly makes use of the sound limb chiefly, resting the weight of the body almost always upon it. The nutrition bears proportion to the exercise, while the other limb, almost unemployed, wastes, in consequence of its inactivity.

Now this atrophy takes place in two different ways, which have hitherto been confounded, but which ought to be distinguished. 1. The limb wastes in length; 2. It wastes in thickness. The wasting in breadth is but little manifested in the skeleton, though much in the muscles, and hence the weakness and thinness of the limb—a vexatious circumstance, it is true, but one which may be remedied by calling the parts into exercise. The atrophy as to length takes place both in the bones and in the muscles, but it is developed in the skeleton, which is most important, and thence proceeds a shortening of the limb, which no remedy can cure. The difference in length between the limbs increases in direct proportion to the age. Not perceptible at birth, it becomes obvious some years after, and at the age of ten M. Dupuytren has always found it well marked, and still more so at twenty, if no means of prevention have been adopted.

The shortening of the muscles and tendons, less considerable in general, becomes nevertheless irremediable after a certain time. Thus at twenty years the tendo-achillis has so lost its due length that when the foot has been brought to its natural direction the heel continues to be pulled upwards, so as to oblige the individual to have a very thick sole to the heel of his shoe, in order to be able to rest at all upon the part. It is therefore desirable to prevent as much as possible this shortening of the bones, because when it once takes place it is irremediable. According

to these views, M. Dupuytren requested several practitioners who devote themselves especially to such cases, to begin the treatment immediately after birth: he sent four or five infants of very early age to an establishment for "Orthopedy," where they remained not more than five or six weeks. The deformity was completely corrected, so that the children learned to walk in the usual manner, and the limb never having lost its length, performed its functions in the usual manner. I witnessed the results, said M. Dupuytren—I kept the individuals in view—and ascertained that the deformity did not return; and I affirm that, by treating club-foot thus early, the wasting of the limb may be avoided with certainty.

It may be added, that the younger the infant is the more readily will the foot yield to pressure. In a new-born babe the hand of the surgeon is sufficient to restore its natural form to the foot, and that without causing any pain. A few months more, however, increases the difficulty, and when the patient has passed his tenth year, machinery is required to accomplish the end in view. After twenty, even mechanical contrivances fail to be of service. This depends upon three principal circumstances: 1. the suppleness of the ligaments and muscles, which continues to diminish as the age increases; 2. the increase of the deformity itself; 3. the imperfect conformation in which the bones are developed; which last is decidedly the most powerful cause.

In conclusion it may be stated, that the treatment of club-foot, if undertaken at birth, is easy and simple: it is both completely preventive and curative.

GENERAL DISPENSARY.*

Chronic Inflammation of the Bladder successfully treated with the Pereira Brava.

Richard Taylor, aged 25, was admitted, under the care of Mr. Coulson, May 18, 1832. The symptoms which he was labouring under at the time of his admission, were a dull aching pain in his loins, uneasiness in the region of his bladder, occasionally extending along the urethra to the external orifice; an incessant desire to make water, each effort being attended with pain and difficulty. The patient said that the urine at times contained a good deal of adhesive mucus, as well as blood. He was sounded, but no stone could be felt, and the urethra was free from stricture. The man had been under medical treatment since the beginning of November, 1831, and all the usual remedies had been tried, but without success. His health was considerably impaired. Six leeches were ordered to be applied to the pubes, and an infusion of the pareira brava (in the proportion of six drachms of the root to a pint of boiling water) was prescribed, of which he was directed to take two table-spoonfuls three times a day. The leeches were repeated five or six times, and tartar emetic ointment was rubbed in for a few times on the pubes. These were the only means employed in addition to the infusion of the pereira brava, which he continued taking (with the intermission only of a week or two) till the 4th of July.

The patient strikingly improved under this plan of treatment; but it was suggested that the amendment might be attributable to the leeching and counter-irritation, and not to the medicine: the medicine was therefore discontinued, and his former symptoms immediately returned. In July, the decoction was ordered instead of the infusion. An ounce of the root in a pint and a half of water, boiled down to a pint, was the strength employed; and to half a pint of this, two drachms of copaivi, with some mucilage, were added: this was ordered to be taken as before. The patient has continued taking this mixture up to the present time, and he finds himself, whilst taking it, free from any bad symptom. On his first application he used to make water upwards of twenty times a day, and very little each time; now he only voids his urine three or four times a day, and makes a pint or more at a time. The patient fears that he shall never be able to do without the medicine, as he finds the symptoms of his complaint return when he discontinues the remedy. In fact, where chronic inflammation of the bladder is the primary affection, the surgeon seldom succeeds in effecting a complete cure. The complaint may be kept under, as in this case, but there is always a great tendency to a relapse.

Mr. Coulson is trying the pareira brava at this time, in some other cases of chronic inflammation of the bladder, and with apparent good effect. He was induced to try this remedy from the observations of Mr. Brodie, in his Lectures on Diseases of the Urinary Organs. The form in which Mr. B. recommends it to be used, is as follows:—"Take half an ounce of the root of the pareira brava, add three pints of water, let it simmer gently near the fire until reduced to one pint. The patient is to drink from eight to twelve ounces of this decoction daily."

Operation for Stone.

Silas Maggs, 12 years of age, and of a delicate constitution, was admitted, under the care of Mr. Coulson, September 5th, with symptoms of stone in the bladder. The

* This short article is in the old type, having been intended for the concluding Number of last volume.—E. G.

mother says, that about eight years ago the child first complained of difficulty in passing his water, and that this symptom has continued, with little or no intermission, up to the present time; a good deal of blood being sometimes voided with the urine. During the last month, the child had been under the care of an intelligent surgeon, and his health, which had suffered considerably, was much improved by the treatment to which he had been subjected. The child had been sounded, by the same practitioner, three or four times, and a stone distinctly felt. A peculiarity in the case was, that sometimes a calculus could be felt and at other times it could not; and this had caused the operation to be delayed. The boy was of a very irritable habit; the urine was alkaline, and contained some adhesive mucus. On the 8th the child was sounded, but a stone could not then be felt; the boy, however, had emptied his bladder just prior to being sounded. As the child's health was in a better state than it had been for some time before, and the parents were anxious for the operation to be performed, it was determined upon for the next day, if the stone should then be detected. Some castor-oil was given early on the following morning, and a clyster administered two hours before the time fixed.

Sunday, September 9th.—Mr. Coulson again sounded the child, when a stone was distinctly felt. The operation was immediately performed, and a calculus composed of the phosphate of lime, of the size and shape of a large peach-stone, was removed. The operation was completed in two minutes. The child was then put to bed, and an opiate given. Very little blood was lost, and the child is rapidly recovering, not having had a bad symptom.

MEDICO-CHIRURGICAL REVIEW *versus* THE WEST-END.

We have received a letter from "A West-End Pupil," entreating us to defend the School to which he belongs, against some "injurious reflections" in the last number of Dr. Johnson's journal. We are very sorry we cannot oblige our young friend by entering upon the subject,—not attaching quite so much importance to it as he seems to do. Besides, by his own shewing, it is unnecessary, as Dr. Johnson has himself taken care to prove, that his own opinion is at variance with that of his reviewer. "Has he not (asks our 'Pupil') at successive times entered two of his own sons at the School in question, and under the very men who are still there? has he not filled twenty mortal columns of his present number with Cases and Reports from the institution alluded to? and does he not formally announce his intention of continuing "in each succeeding number" to favour us with "lengthened and interesting" clinical observations from the same quarter, notwithstanding that his reviewer has taken a pathetic leave of the place in a lachrymose Latin valedictory?" We dare be sworn the Doctor knew no more of the paragraph complained of, than he himself informs us he did about the attack on Mr. Arnott, in his previous number. As to the rest, our correspondent need not distress himself—the public, he may be assured, set down such "reflections" precisely for what they are worth.

MR. DAVIES.

Mr. David Davies has been appointed Surgeon in Ordinary to Her Majesty's Household, in the room of Mr. Keate.

CUTANEOUS DISEASES.

Lecture III.—Part II.

EXANTHEMATA.

Urticaria.

The next disease, gentlemen, of the description in which the inflammation is extended in patches on the skin, and of which I will speak, is urticaria. I select it the next because it is not a contagious disease, and, indeed, is almost always a disease free from danger, just like the three I spoke of in the class of papulæ—namely, strophulus, lichen, and prurigo; and just like the two of which I have already spoken in this class—viz. roseola and erythema, excepting E. tuberculatum, which certainly does, although it will not itself prove fatal, occur in persons who usually soon die of something else.

This disease, urticaria, is in plain English the *nettle rash*. It is so called because the appearance is precisely that of a person stung with nettles,—*urtica* being the Latin for nettle. You find it spoken of by some writers under the term *essera*, which, I understand, is the Arabic name. I think Dr. Heberden speaks of nettle rash under that title.

In this disease there are efflorescences, as they are called—extended patches; but besides that there are wheals. I need not say that a wheal is a pretty hard elevation of the skin, such as occurs from a horse-whip applied to the surface of the body; but it is defined particularly by Dr Willan, to be a rounded or longitudinal elevation, he says, of the cuticle; but one ought to comprise more in it than that: we might say in general terms, of the skin; but still "not permanent, not containing fluid, not tending to suppuration." Of course, if the cuticle be raised, according to Dr. Willan's expression, there must be something in it; you would imagine there to be a vesicle, water, or pus; it is, therefore, improper to say elevation of the cuticle. The cuticle is raised; but you would have a wrong idea if you imagined that the cuticle was raised from the other component parts of the skin. The cellular membrance is raised indeed, as well as the cutis, and there is a hard bump, and an extended efflorescence or patch, or whatever you please to call it, around the bumps. This efflorescence is of a vivid red—a very intense red—sometimes really of a damask hue—almost the appearance which you observe in those persons said to have claret marks; occasionally there are a few very small wheals, but sometimes not, the efflorescence being the character of the disease, though in the greater number of cases, in the efflorescence you find these wheals, which look white in the midst of the red patches. There is an extreme itching—that sort of itching which is called tingling, exactly as if a person were stung with nettles. To the eye of a bystander, and to the feelings of the patient, the state is just that of a person stung with nettles.

Species.—If the bumps be very hard indeed, they are much larger at the same time; and that variety of the disease has a particular name, and is called *U. tuberosa*. It is sufficient to remember, that sometimes the bumps are pretty large and hard, and very painful; and if you choose you may remember, that when they are so it is called U. tuberosa. These large ones, these thumping bumps, chiefly occur

in the loins and legs, and are generally worse at night, subsiding in the morning and leaving the patient weak. If it happen that these wheals and patches are numerous, and coalesce, and of irregular forms, is is called *U. conferta;* and these are said to occur chiefly in persons of a dry, swarthy skin, above forty years of age. If it so happen that the disease has been preceded or is accompanied by headache, nausea, gastrodynia, drowsiness, feverishness, pyrexia,—altogether it is called *U. febrilis.* Very frequently, whether it is preceded by these symptoms or not, it is attended by them when it does appear. If they precede it they will still continue; but frequently they will come on only when it comes on. Generally, in severe cases, there is heat and thirst; the tongue is white, yellowish, and loaded; the epigastrium is tender; the pulse is full and quick; and now and then the disease will come on like any other inflammation, with shivering. Now and then the internal symptoms, which occur before the eruption, are relieved by it, or at least are diminished, or disappear; but they re-appear when it ceases again. Frequently, however, these will all exist together—the internal symptoms of feverishness, and the external symptoms of efflorescence and wheals.

This disease is sometimes so active, that the face is swelled altogether, and the eyes are almost lost. Persons say they can hardly see out of their eyes, and, in fact, you can see but little of their eyes, and every part around is swollen—cheeks, lips, and scalp; and all are tense, the nose among the rest. The eruption will vary in intensity, and vary in its situation, not only on different days, but at different hours of the same day; it will come and go several times in the twenty-four hours. Warmth will aggravate it, and, on the other hand, exposure to cold will do just the same. When a person undresses, and there is an application of cold air to a part of the surface which before was covered, it will frequently bring out the rash, and make it worse. On the other hand, if a person go into the other extreme—if he stand near the fire, or take stimuli, he will be worse. I need not say that rubbing and scratching make things a great deal worse, but people will do so, and on account of the pain they really can hardly help it. This disease is often not confined to the surface; it affects the internal mucous membranes next the surface, and the submucous cellular membrane. You will often find the tongue, the fauces, and the throat swollen, so that the patient can perhaps hardly swallow. The irritation of the mucous membrane in that quarter of the throat sometimes occasions a degree of cough; and it is said, but I have never seen it, (though I have frequently seen patients unable to swallow, and nearly unable to breathe) that now and then there is an irritation of the bladder, producing strangury, and sometimes diarrhœa is induced. The internal affection in the complaint is sometimes said to end fatally; but I presume this does not arise from the eruption; on the contrary, I imagine that it is the general state which gives rise to the eruption. The disease will last for a few days, perhaps a fortnight, and now and then there is a slight scurf afterwards. The cuticle, from the irritation, is separated from the parts beneath, and comes off in the form of slight scurf; this occurrence, however, is not a general thing.

Sometimes the disease is chronic, called *U. perstans.* It is sufficient to remember that it may be a chronic disease. The redness will go, but the wheals, perhaps, will remain. Now and then, instead of remaining chronic, it comes and goes for many months, vanishing and recurring, and then it is called *U. evanida;* but I beg you will not trouble yourselves to remember these expressions. If you know that it comes and goes, or stays, that is sufficient, without knowing how authors arbitrarily choose to designate these varieties. Dr. Bateman says there is no pyrexia, but I know that there frequently is, and also an inflammatory state of the head and of the abdomen. It sometimes happens that the eruption disappears, or only comes from time to time; and when the tingling comes between the appearances of the disease, it is then called *U. subcutanea.* You perhaps cannot well imagine a disease of the skin to be under the skin, but so it is called; it lies underneath and teazes the patient without shewing its face.

Perhaps, before I proceed to consider the causes, I had better shew you the appearances of the disease. It is an affection which people very often do not recognize. I know that it occasionally occurs in practice that a patient is said to have any thing but urticaria, and is very much frightened; but it is easily recognized by the tingling and by the elevations or wheals. The affection is represented in plate xxiv. figs. 1 and 2. You see in both forms of the disease that the wheals are slight; in the upper figure there is a slight inflammation, and in the lower one it is very great; it is as deep as damask, or claret marks. You sometimes see the redness with a few wheals; and people are often said to have erysipelas when they have only this; and there is frequently a swelling of the face too, so shat some persons are very much alarmed. It occurs sometimes in children, and in them it may be more easily mistaken at first than in adults. It may be, in the first instance, mistaken for measles,

or some other disease: it is often called erysipelas.

Causes.—I believe that the most frequent cause of urticaria is the application of cold, especially when the body is heated. It will frequently arise from cold applied to the surface—sometimes cold and wet, but especially when the body is over heated. It is perhaps sometimes induced by sudden heat. It will frequently arise from an emotion of the mind; it arises too from teething, and we see it too continually from certain ingesta; some have it through one kind, and some through another. In some, almonds will occasion it, or rather the skin of almonds. It is not the blanched almonds that cause it, but the unblanched, so that it is the external part that produces the disease, and the disease is induced in consequence of the skin of the almond containing hydrocyanic acid, which now and then will have the same effect. Various kernels of fruit will give origin to it in some people, in consequence of containing the same substance. Mushrooms, also, will occasion it in some people: I suppose peculiar kinds. Herrings, particularly red herrings, and shrimps, will occasion it. Shell-fish are very often the cause of the disease, but I believe muscles produce it more frequently than other kinds. You hear of persons being poisoned with muscles, and they are said to swell. I imagine the idea of swelling from being poisoned arises from this circumstance, that urticaria is produced by different substances; and when it is produced, the face often swells prodigiously, and even the whole body; and if persons have previously eaten muscles, they are sure to say they are poisoned: it is not worth the name of poisoning. So intense is the idiosyncracy of some persons in this disease as to muscles, that a gentleman informed me that he knew a woman in whom urticaria was induced by one tea-spoonful of the water in which muscles had been boiled. She always had urticaria if she tasted muscles; but having boiled some for her husband, and being extremely fond of them, she thought she might indulge herself with a little taste of them, and so she took a tea-spoonful only of the liquor, but it had the same effect. Crab-soup, which I suppose is much the same as the liquor in which muscles are boiled, will also induce the disease. Malt-liquor, white-wine vinegar, and common spirits, will, in some people, produce it. A medical man told me that his wife always had it if she took gruel. One of the most common causes in medicine is copaiba. Many persons on taking copaiba are covered with nettle-rash. I had a patient in whom it was produced in the greatest intensity I ever saw it, by the sulphate of quinine. I never knew this before; his eyes were closed; his face was so swollen, that his friends did not know him; he was in a most intense burning heat, and could scarcely breathe; swallowing was impossible. His brother came to me, and told me of the circumstance. I wished to ascertain whether it was the sulphate of quinine, and I begged him to take only a grain: he complied with my request, and it had the same effect, only in a less degree. He then took a minute fraction of a grain; there was not more quinine than, as common people say, was sufficient to swear by, and even that produced a degree of uneasiness in his throat, and a certain tingling in his skin. I have known several persons in whom the disease has been induced by landanum; in fact by opium in any common form. I mentioned that in my own case, whenever I take opium, I am sure, in two or three hours, to have an itching of my nose, which will not leave me quiet for several hours. The same substance in other persons will induce universal tingling of the skin, with bumps—in fact, nettle-rash. Pepper, and various spices, will have the same effect. Pepper and vinegar occasion in me a great itching of the scalp. I once saw the disease induced very violently by a mixture of subcarbonate of iron with treacle: whether it was the iron or the treacle I do not know. The effect of copaiba in inducing the disease is very common: a large number of people always have it if they take this medicine. External stimuli will induce it, and it may spread along the skin, so as to prevail to a considerable extent. Dr. Willan says that he knew a person in whom it was produced by a slight application of ung. hydrargi., and another who had it from rubbing the hands with oatmeal. It is worth notice, that when an irritant is applied to the skin, the effect is not always limited to the spot, but other parts, either around, or *to* some distance, or *at* some distance, may suffer. Croton oil often causes redness and vesicles far beyond the spot of application. Tartar emetic applied to the legs often causes pustules in the genitals. For this fact I beg to refer you to a paper of mine in the 13th volume of the Medico-Chirurgical Transactions, on Subcarbonate of Iron.

Treatment.—In regard to the mode of treatment, if the patient's strength will bear it, the shortest way is to take blood from the arm. Even if any thing improper have been taken into the stomach, by bleeding in the arm you produce almost instantaneous relief, and the patient will speedily get rid of the complaint. A friend of mine was taking copaiba, through his misdeeds, and the next day was seized with an eruption all over his body. His face was swollen and burning, and his lips were so stiff that he

could scarcely move them to eat. The aperture of his eyelids became very small; his pulse was about 100, and full; he was in a great heat, and red all over. Before I saw him he had taken an emetic to empty his stomach, but it was quite in vain—the copaiba had entered his system, and was there causing irritation. When I went to him, I immediately saw it was nettle-rash, and I begged another friend who was by to put a lancet into his arm, and detract a quantity of blood. Before the bason was half filled he felt relief, and as the blood continued to flow he felt more and more benefit; he became paler and paler, the swelling of his face declined, and before evening he was tolerably well. He took a dose of physic to assist the bleeding, but I dare say he would have done without it. The venesection, notwithstanding the emetic had been fruitless, instantly relieved him. A short time afterwards he found it necessary still to go on with the copaiba, his other troubles not having ceased, and the same effect was again produced. He took no emetic that time, but was again bled, and the disease instantly disappeared; he had no further trouble. However, if you are sure that the cause is still in the stomach, in consequence of the short time which has elapsed since it was taken, it would be but common sense to empty it; but I confess, if the person were of full habit, I should take away blood first, for you will find that a most speedy mode of cure. You must, as in all other inflammatory complaints, regard the constitution of the patient on the one hand, and the intensity of the disease on the other. If you take away blood, you will cure the disease in perhaps a twentieth part of the time that you will if you trust to low diet and purgatives. I would in every case back bleeding by low diet and purging. In the chronic form of the disease, the patient should avoid stimuli, and adopt antiphlogistic regimen; he should avoid eating any thing that can excite either his body or his mind; and if the pulse be strong, he should unquestionably lose a small quantity of blood. The warm bath is said to relieve the affection, and in some cases bathing has done good. Bark and acids are praised. All the cases, however, that I have seen, whether acute or chronic, have been best and most successfully treated by venesection and common antiphlogistic measures. In the case of the lady who had urticaria from taking the subcarbonate of iron in treacle, for a couple of days, the eruption began one Sunday morning, and it was supposed that she had got scarlet fever. The eruption was just of the appearance you saw in the lower figure, of a damask red, with bumps, and it came out suddenly. She was in the greatest agony; her countenance expressed great distress; but though I imagined it arose from the medicine, I did not give her an emetic; but I had her bled, and in her, while her noble blood flowed, (for she was a peeress,) the symptoms declined, and when the arm was tied up, there was no redness to be seen. No pains were taken to get rid of the offending matter, which, in all probability, was the cause of the disease. I did not know the use of bleeding in this complaint when I began practice, but I found it mentioned in authors; it seemed rational, and I adopted it in every case afterwards where the pulse would allow it. In the chronic form, if you find any other disease present, you must endeavour to remove that. The urticaria may arise from chronic enteritis or gastritis, and that ought to be remedied in the usual way, and that usual way is to apply leeches to the abdomen, or adopt general bleeding, &c. You may get great and deserved credit for curing this disease; or you may find it very obstinate. The secret of the cure lies generally in bleeding and adopting antiphlogistic means. The chlorides, prussic acid, or nitric acid, best alleviate the itching, among local applications.

Rubeola.

The next disease of which I shall speak is a severe affection, is frequently fatal, and is contagious; namely, the measles.

Etymology.—This is called among the medical men of this country, *morbilli*, or *rubeola*. We have adopted the expression "morbilli" from the Italians, who so named the disease from its being a less kind of plague—the minor plague, the little disease. The expression "rubeola" was formerly applied to scarlet fever and measles in common, and to other diseases; in fact it was Sauvages, the first writer on methodical nosology, that restricted the term rubeola to measles. The word *rubio*, from which it comes, is Spanish, and it was first written *rubiólo*, as it is pronounced, the accent being placed on the *o*.

This is a contagious and infectious disease; it chiefly affects children, and is more severe in them than in adults. There is very rarely an indisposition to it; most persons are liable to it; you rarely meet any one that will not take it. The indisposition is less frequent than the indisposition to small pox. It rarely occurs more than once, but sometimes it does. Dr. Baillie, in the Transactions of a Society for the improvement of Medical and Surgical Knowledge, describes eight cases of its occurrence more than once. When it does occur more than once, it is generally when it prevails as an epidemic disease. By epidemic I do not mean contagious. The word epidemic has been attempted to be restricted to those diseases which prevail over a number of

persons, without any contagion in the atmosphere; but the word relates to diseases that prevail temporarily over many people without a local cause, be it contagious or not contagious. It is said to have been observed at birth. Hooping-cough, I mentioned, has been heard at birth. Children have been frequently born with the small pox; and it is said that children have been born covered with measles. It chiefly prevails in winter and spring.

Symptoms.—Now this disease is very well characterized; it has very peculiar symptoms, and it is a disease that hardly any one, I think, can mistake. It is almost always ushered in by catarrhal symptoms, that is by a flushing of the face; redness of the eyes; heaviness of look; a running of the eyes and nose; soreness of the throat; sneezing; cough; a hoarse and sounding cough—a cough which old women who have been much amongst children, describe as the "measle cough." I cannot describe it—I can only say it is a hoarse cough.

Course of the Disease.—These catarrhal symptoms will sometimes last two days, and sometimes twenty, before the cutaneous affection shews itself; but in general it is on the fourth day that it appears—sometimes as early as the third, sometimes on the fifth, and sometimes on the sixth. It is upon the face generally that the cutaneous affection presents itself; it appears by a rash on the forehead and the chin, and from thence it spreads itself all over the face. The next morning it is found to have spread, not only over the face, but over the breast and trunk, and upon the extremities. On the fifth day the disease has pretty well covered the body, and it is on that day that the face is most vivid. On the sixth day the eruption is pale on the face, and most vivid on the body, and on the seventh day it begins to disappear in the latter situation. The disease altogether is of about seven days' duration. The catarrhal symptoms appear for four days; upon the fourth day the cutaneous disease appears, and this lasts three days—making seven altogether. But now and then children have catarrh for two or three weeks; and then, in the midst of the catarrh, without any previous additional symptoms, except perhaps an increased intensity, the cutaneous disease shews itself. Now and then there are patches on the back of the hand, which have not appeared before the sixth or seventh day of the fever; and in the remote parts of the body the redness occasionally does not come on till that time, and then the eruption in these situations does not decline, perhaps, till the eighth day. On the ninth day there is only a slight discolouration left—a sort of brownish appearance. The colour in this disease is by no means so vivid as in roseola, and as in scarlet fever. When it is all over, if the inflammation have been pretty extensive, there is a furfuraceous desquamation. This, then, is the course of the disease.

When the affection first appears, there are only, at the utmost, little red dots, scarcely perceptible and nearly circular: they are rather less than the spots of fleabites. They become more and more numerous, however, and coalesce into patches. All the exanthemata begin and extend in this way. The patches which are formed in this disease, you must remember, are of an irregular figure, and frequently assume a semicircular or crescent form. This is characteristic of the disease, and it is worthy of notice; not that the diagnosis is often at all difficult, but if it be difficult you may be assisted by remembering that the patches in measles affect a semicircular or crescent form—that in the midst of these patches there are circular spots, and that around the patches are spaces of the natural colour. Upon the face the disease is, of course, the most severe. The skin of the face is finer, and more abundant in red vessels, than that of many other parts; there it is that the effects of inflammation are the most severe; and from these circumstances the skin is not smooth, but roughened, so that if you pass your finger along it you will find a little roughness—hardly worth the name of roughness, but inequality. Occasionally, if the inflammation be severe, this is observed in other parts of the body. Occasionally you will find the red dots more or less hard and elevated. Notwithstanding the disease is characterized by patches, the inflammation may be so intense as to cause the face to swell and the eyes to be closed; nay, the symptoms may be so severe as to cause little collections of water, the size of millet seeds, which are called *miliary vesicles*; and sometimes there are papulæ on the hands, wrists, and fingers, elevations of the cuticle, having a distinct roughness in the midst of the patches; so that while the patches give an elevation to the feel, distinct from the surrounding skin, in the midst of these there will be another roughness arising from the papulæ. When you hear a child sneeze and cough, and see these crescent semicircular patches represented in plate xix. you may be sure it is the measles. It is on the face you usually see the disease best characterized. You may mistake it on the arms, hands, and body, but you can hardly do so on the face. It is very important to make a correct diagnosis here, although the disease may be of a slight character; because if you tell a parent that the child is about to have the small pox, when it is

going to have the measles, of course you will be thought no doctor. Sometimes the spots will go down as fast as they appear.

In this disease it is almost constantly observed, that the cartarrhal symptoms are not much lessened on the appearance of the eruption. You will find it often said by authors, that when the eruption comes out in cutaneous diseases, the internal symptoms are relieved. We all meet with this occasionally; but in a great number of cases of cutaneous diseases, I have seen the internal symptoms not alleviated by the appearance of the external. In measles, however, it is a well-known fact, that so far from there being an alleviation of the internal symptoms, they are more frequently aggravated than not; at any rate, in general, they are not mitigated. When the eruption comes out, the catarrh is confined perhaps to the bronchiæ. It appears that the catarrh is more or less bronchitic, for there is an affection of the superior parts of those tubes. But frequently the irritation of that part of the membrane below the larnyx increases so that you have decided bronchitis. Sometimes you will have an affection of the substance of the lungs—peripneumonia; and sometimes of the investing membrane—pleuritis. Frequently, when the measles are over, they leave chronic bronchitis, chronic peripneumonia, chronic pleuritis, and even phthisis: they frequently seem to give rise to tubercles. Frequently, too, there is left after measles a chronic diarrhœa, which is generally of an inflammatory character; frequently inflammation of the eyes—ophthalmia; affection of the ears—ear-ache, running of the ears, otorrhœa, deafness; frequently disease of the mesenteric glands; frequently, too, after the disease will come chronic cutaneous affections—such as ecthyma, rupia, porrigo, boils, aphthæ, and many other things; in fact there is no end to the mischiefs that measles leave behind. They may recede suddenly, and then internal inflammation take place of the lungs, or within the abdomen, or in the head; but it is chiefly in the chest that inflammation occurs when the disease recedes.

Now it is not by any means certain that the retrocession of the measles causes these symptoms; it is just as probable that, in many instances, the occurrence of the internal disease puts a stop to the external. It is a great mistake to suppose that the retrocession of an eruption causes internal disease in every case where such internal disease occurs. There can be no doubt that the occurrence of another disease in the internal part of the body will put a stop to, or suspend, a disease which has previously been going on in an external part; but it is a fact, that when measles suddenly disappear externally, for the most part there is some internal affection.

Treatment.—The treatment of the disease consists, in ordinary cases, of mild antiphlogistic diet and the other regimen. You must keep the patient cool, but not cold, lest you should induce bronchitis; you must keep him at a pleasant temperature. It was formerly the custom to keep children hot, lest the measles should go in; the consequence of which was, that it kept up an irritation of the whole system, and kept up any bronchitis that might be present. On the other hand, I should not aim at keeping the patient cold, lest there should be bronchitis induced in this way. An intermediate plan seems to answer best. Some have recommended cold affusion in this disease; but the tendency to bronchitis is such, that I have never practised it, and I would not recommend it.

From the catarrhal symptoms in this disease, and their great disposition, on the appearance of the eruption, to become severe, you will find it necessary always to direct your attention to the state of the chest. It is always necessary to observe carefully whether there is peripneumonia, or bronchitis, or pleuritis, or any other *itis* of the chest, and to treat it just as if no measles were present—to take blood from the arm or the jugular vein, or apply leeches, just as you may think proper. One would not pay such great attention to these symptoms before the eruption occurs, but if they be severe when the eruption comes out, blood should be taken. Leeches generally answer; but if the child be large you might take it from the jugular vein, or the arm. Moderate purging is proper, and low diet. The patient must be treated on the antiphlogistic plan, according to the degree of inflammation. If the eruption does not come out, or recedes, you should put the patient into the warm bath; but you should remember that this is most likely produced by some internal disease, and that internal disease, in nine cases out of ten, is inflammatory; and in eight out of that nine it is situated in the chest. The best mode to bring out the measles again is to lessen the internal disease. The measles will sometimes be suspended for many, many days after appearing on the surface; they will recede in consequence of the internal inflammation; you must subdue that, and then frequently they will re-appear. This is a very curious circumstance. Now and then there may not be internal inflammation; there may be mere debility, and then it is necessary to give stimulants—ammonia with wine. When there is diarrhœa, it generally requires antiphlogistic treatment. The diarrhœa is generally troublesome when the dis-

case is over; but it is important in all cases to press upon the abdomen, and see if there be any tenderness. In a large number of cases you will find tenderness, and the diarrhœa is only to be subdued by sinapisms, leeches, &c. Sydenham pointed out that the diarrhœa was inflammatory; that opium and opiates were improper; and that venesection ought to be resorted to. Venesection is out of the question in many cases, but it is sometimes proper. However, this is no general rule; you see cases where astringents and opium will cure the disease, there is so little inflammation; but frequently they are not to be trusted to alone. In some you must unite this plan with the remedies for inflammation; in others you must solely treat inflammation, and the diarrhœa will cease. This is a most important point in practice, although it is simple, and unless you carefully attend to it, you may do harm when good might be effected.

OBSERVATIONS ON PARTURITION,

TAKEN FROM A

Lecture delivered at the Theatre of Anatomy and Medicine, Marsden-Street, Manchester,

October 3, 1832,

BY JOHN ROBERTON,

One of the Surgeons to the Lying-in Hospital.

(*Concluded from our last Number.*)

THE next argument on which our opponents rest their objections, is the non-existence of scientific midwifery in the civilized countries of Eastern Asia: a fact which indicates, as they contend, that it is regarded *there* as unnecessary. "Among the highly-civilized and numberless ladies and women of China and the East," says Sir Anthony Carlisle, "ordinary matrons are universally employed in the sanctuary of child-birth; and they would revolt with horror from any proposal to admit the presence of a man." In reply to such a statement as this it has been common to argue, that, in warm countries, the parts concerned in admitting the passage of the child are so relaxed, by the influence of climate, that labour becomes comparatively easy; and that hence we are to account for the non-employment of scientific accoucheurs. This I regard as a very unsound view of the subject. In all those warm countries whose inhabitants live after the same manner as the mass of people in England, parturition is in no degree easier than it is here. In the town of Sierra Leone, so near the equator as latitude 8 deg. north, we are assured by Dr. Winterbottom, who resided there, that, having been present at a number of labours, he can affirm that they, in every respect, resemble those of women in the same situation of life in England. I have met (says he) with instances in England, where the fœtus was expelled with more ease than I ever knew it to be at Sierra Leone. Long also, the able historian of Jamaica, assures us (in allusion to parturition among the slaves) that labour is not so easy in the West Indies as (he supposes) it is in Africa; for many children are annually destroyed, as well as their mothers, in the hands of the negro midwives.

While on this topic, I may refer to the prophetical writings of the Old Testament, for many striking allusions to painful parturition. The Jews, you are aware, inhabited *a warm climate;* and yet, were we to judge of the nature of parturition among them, from the very frequent reference which the prophets make to it in figures and similes, when predicting the sufferings to be produced by impending judgments, we should be led to the conclusion that in no people was the *primal curse* ever so severely exemplified. Thus Jeremiah, the coming miseries of Judah passing before his eyes, exclaims, "I have heard a voice as of a woman in travail, and the anguish as of her that bringeth forth *her first child;* the voice of the daughter of Zion that bewaileth herself, that spreadeth her hands." A multitude of other passages, containing a similar allusion, might be cited. In the historical parts of the Scriptures, too, there is incidental mention of several cases in which parturition proved fatal. So much for the relaxing influence of a warm climate!—a notion which, like various others respecting the influence of climate on the human system, is totally at variance with facts.

To return to the proposition that, in China and the East, man-midwifery is unknown: this opinion is certainly countenanced by the several reports of Sir George Staunton and Mr. Barrow, each of whom accompanied an embassy to the Court of Pekin. Mr. Barrow expressly states that there are no man-midwives in China. A writer in the Encyclopædia Britannica, however, has shewn that these travellers are in error. His information, he tells us, is derived from a more authentic source than the works of gentlemen who were only a few months in China, and who, during that time, were treated in a great measure as state prisoners. He has it, through the medium of a friend, from a gentleman who resided upwards of twenty years as surgeon to the British factory at Canton, and who had both the ability and inclination to learn, during so long a residence, all the cus-

toms and prejudices of the natives relative to the preservation of human health. The information is in substance this; that although physic and surgery are, in a scientific sense, unknown in China, midwifery is in a more advanced state, and, that for a long period midwifery has been practised by a set of men destined to the purpose, by order of government. These men, who hold in society the same rank which lithotomists did in this country about a century ago, are called in whenever a woman has been above a certain number of hours in labour, and employ a mechanical contrivance for completing the delivery without injury to the infant. A certain number of such individuals is allotted to each district of a certain population. It is said that the Chinese government was led to make this provision in consequence of a representation, that, annually, many women died undelivered, and that in the majority of cases the cause of obstruction might have been removed by simple mechanical expedients. More need not be said about the efficiency of matron midwives in China and the East.

But, say our opponents, in 99 cases out of a 100 the labours of women, even in civilized Europe, are perfectly regular; and were they left wholly to nature, would terminate favourably. They further insinuate, that as it is only within the last 60 or 80 years that man-midwifery has become general in England, the change must have been brought about, not by any *new* necessity, but by the interested policy of medical men. Admitting, as I readily do, not that 99 in a 100, but that a large proportion of labours (say 19 out of 20) would terminate well, under the eye of an ordinary nurse, were they left solely to the energies of nature, *this* furnishes no argument against man-midwifery.

Waving, as unnecessary, all discussion of the importance of surgical midwifery (by which I mean the operations, manual and instrumental, requisite in difficult and dangerous parturition, and in those accidents which may precede or follow it—operations which, speaking generally, man-midwives are alone fitted to practise,) I beg to call your attention to the great and important principle upon which my apology for scientific midwifery rests: it is, that *the natural progress of labour is less interfered with in proportion as obstetric science advances.* It betrays little knowledge of mankind to imagine, that simplicity, in the practice of any art or science, is the characteristic of untutored ignorance. Simplicity in this sense, which is only another name for a profound acquaintance with nature, is of slow growth. This is amply verified in the history of midwifery. In tedious labour, among the American Indians, for example, it is the custom to fasten a belt round the abdomen of the patient, and powerfully tighten it, with the view of forcing out the child; or the woman is lifted by her assistants and violently shaken; or when other means fail, they bind a handkerchief over her mouth and nose; and this, by causing a general convulsion, sometimes actually produces immediate delivery. In similar cases among the negroes, we are informed, by Dr. Winterbottom, that it is common to suspend the woman by the heels, with the view of altering the position of the child. They sometimes also, like the Indians, employ compression on the abdomen by means of a circular fillet, which is tightened with great force by a dozen assistants. Other practices are in use in rude nations; as the employment of terror, to produce which, the attendants, on a sudden, raise a great shout—tickling the nose, to excite violent sneezing; and many besides—more than I shall trouble you by enumerating. The methods adopted to obtain the expulsion of the placenta are equally strange, and not less rude.

In the practice of rural midwives, in our own country, who are generally uneducated, it is scarcely credible to what an extent they carry their interference in every stage of labour. It is no part of their system to trust in the unaided powers of nature. They must needs be "giving help." Sometimes they rupture the membranes at an early period. Many, again, on the occurrence of every pain, introduce their fingers and pull back the perineum, in the belief that such a practice increases the bearing effort. This, by producing a dry inflamed condition of the vagina, occasionally suspends labour altogether; and is followed, after delivery, by severe irritation of the parts. In many cases, hot spirits, or hot spiced ale, is forced upon the patient; and this too, by producing fever, will often completely suspend the labour. It is, however, in the last stage of parturition that the uninstructed midwife is most busy. On the recurrence of a pain, and often when there is not a pain, the patient is loudly urged to hold in her breath and to bear down—a practice which sometimes leads to considerable exhaustion. The instant the child's head is born, the midwife has now a greatly increased opportunity of giving help; so think the bystanders as as well as she. To what purpose is the presence of the midwife, if the patient is to remain in suffering, and the child to linger in the birth? This is popular logic, and quite satisfactory to the midwife. She accordingly delivers the shoulders; it may be at the expense of a lacerated perineum; and the lower parts of the child are made to follow with still

more ease and rapidity. The speedier the labour is terminated, the more adroit, of course, is the assistant. The funis is forthwith divided, whether the child be lively or otherwise: and now the extraction of the placenta is all that remains for the exercise of her skill. This the midwife often accomplishes with more rapidity than safety to her patient. Having twisted the funis round her finger, or seized it in her hand, by means of a dry cloth, and directed the patient to hold in her breath, or to cough, she begins to drag; and one, at least, of these six consequences follows: either the placenta is safely removed, which doubtless often happens; or irregular, spasmodic, action of the uterus is excited, and the placenta thereby strongly retained; or the funis breaks, and there is an end; or the placenta being torn from the womb, in the absence of contraction, alarming hæmorrhage ensues; or, the placenta being morbidly adherent, the midwife is foiled; or, should the funis and the midwife happen both to be strong, and the placenta, as in the last instance, morbidly adherent, inversion of the uterus is the result. Such is a picture, and a very faint picture, of practical midwifery, in the absence of scientific knowledge.

I have already admitted that a large proportion of cases of labour would terminate well, unaided, under the eye of an ordinary nurse; but even here, in many of the instances, to the completion of which the natural powers are adequate, at the expense of long and severe suffering, science lends her aid in a most effectual manner. It is not in what has been accomplished by bringing so near to perfection the resources of surgical midwifery, that science most brightly shines, but rather in the safe and easy expedients which it has devised for diminishing, both in duration and intensity, the ordinary sufferings of childbirth. In labours strictly natural, terminating after a few hours of moderate suffering, scientific midwifery is passive; its interference extending only to the division of the funis. But in lingering, or in acutely painful parturition, the following, among other expedients, are of its devising; all devoid of pain, and all more or less effectual, provided they be directed, in their application, by a mature experience:—

1. In many cases, in the early stages of labour, it is of great importance to the safety of the patient that she be maintained in some certain position, in order that the uterine action may bear upon the fœtus in the direction of the axis of the pelvis: the proper position, whatever that may be, science alone can point out.

2. When the os uteri is thick and rigid, the pains severe and incessant, and the dilatations low or suspended, science interposes; and by means of the lancet, or the local application of belladonna, affords relief.

3. In metastatic labour, *i. e.* when the pains are not uterine, but seated in the loins, abdominal muscles, nates, &c. science has devised relief in the employment of friction, pressure, and under particular circumstances, the administration of laudanum.

4. In certain instances of suspended labour, *i. e.* where the regular pains have ceased and there is more or less of fever, science directs the employment of stimulating lavements, with frequent success.

5. In obliquity of the mouth of the womb, and other instances, when the pains, although severe, have no dilatating effect, the well-instructed accoucheur can give efficient aid by supporting with his finger the anterior lip of the os uteri, and thereby causing to bear upon its entire circle the equal pressure of the presenting part, whether that be the bag of membranes, or the head of the fœtus.

6. In some kinds of lingering labour, science has discovered medicines which are effectual in expediting the progress: such are the ergot of rye, and small stimulating doses of laudanum.

7. It has also discovered that lingering labours may often be speedily terminated by the well-timed rupture of the membranes.

8. By free lubrication of the passage, particularly in the latter stage of first births, the exit of the head is greatly facilitated; a remedy this, simple though it may seem, productive of much alleviation of suffering, while it likewise lessens the risk of perineal laceration.

9. In tedious labours, the comfort and safety of the patient are equally secured by the regimen, particularly the administration of cordials, being under the direction of science.

10. And how important is the negative aid, if I may so call it, which is afforded to the patient by the mere announcement, at an early period of labour, that all is right!—an announcement which only the scientific practitioner is warranted in making.

11. In the management immediately following the birth of the child, the importance of science is pre-eminently displayed, in the security it provides against hæmorrhage, as well as in contriving the safe and speedy expulsion of the placenta.

But the objector with whom I am contending will ask, cannot a matron practise these expedients; and if so, where is the use or propriety of such a class of practitioners as men-midwives? I reply, doubtless a matron may practise many of these expedients, if they have been taught her.

It is of the value of midwifery, as a science, originating with and practised by men, compared with matron or uncultivated midwifery, of which I have been speaking. A certain proportion of instructed female midwives in a community may, for aught I know, be a benefit. But what I am contending for is, that until the period when men practised midwifery, as a branch of the medical profession, it was never practised scientifically; and surgical midwifery remained stationary for centuries, at once rude in its operations, barren in its expedients, and murderous as respects the fœtus. A strong proof of the truth of this, we have in Denman's declaration, in his old age, when speaking of the employment of the forceps. "In my younger days," says he, or words to that effect, "instruments were used 20 times oftener than they are now." In fact, when midwifery was in the hands of matrons, men were called in to the lying-in chamber only in those cases which the midwife pronounced to require surgical assistance; and the surgeon himself, having no correct knowledge of the natural progress and successive stages of labour, or of the wonderful powers which nature exerts for its completion, in even the most uncompromising cases, had no other course but to apply his instruments; and so terminate, as he best could, a process which probably needed no other helps than patience on the part of the attendants, and the soothing stimulus of hope in reference to the patient. But no sooner did the practice of midwifery pass from the matron to the educated accoucheur, than both it and its kindred branches,—the diseases of women and children—by happening, in many instances, in this country, to fall into excellent hands, were cultivated with unequalled success. The mortality incident to childbed, in the course of half a century, diminished to at least one half of what it had been: and the result is, that this department of medicine, at the present hour, rests more unequivocally upon a scientific basis than any other.

You cannot, I should think, but be aware that some, even persons of note, and chartered bodies too, of high rank in the profession, have feigned to regard midwifery as a degrading pursuit. Were you to ask me why—I should not be able to inform you. Certain it is that midwifery is not altogether exempt from repulsive features. The throes and sufferings of the feebler sex, abstractedly considered, have nothing in them attractive. But what is there more attractive, I would gladly know, in the long list of diseases engendered by vice and luxury, to the practical study of which these dignified men give their days and nights? The truth is, the unkindly feeling I have alluded to is rather a corporate prejudice than one attaching itself individually to educated men. The names of Harvey, Smellie, Hunter, Hamilton, Denman, and others of perhaps equal repute, who have practised and advanced the science of midwifery, are a sure guarantee that it is a pursuit neither mean nor unattractive.

In conclusion, I would have you bear in mind what I presume you must have gathered from the tenor of this lecture—that women (and of course all that concerns their safety and welfare) are more highly regarded in proportion as mankind advance in moral culture and in civilization. This is the sole reason, and a more honourable reason need not be alleged, why scientific midwifery is of modern origin, and why it is as yet confined, in a great measure, to the more enlightened of the nations in Europe and America.

REMARKS

ON

ENLARGEMENT OF THE PROSTATE—DELIRIUM TREMENS—UTERINE HÆMORRHAGE.

To the Editor of the Medical Gazette.

SIR,

THE following notes, concerning the Enlargement of the Prostate, Delirium Tremens, and Uterine Hæmorrhage, have been gleaned by chance at the bedside, and deserve to be recorded only among the stores of miscellaneous information. A medical journal, or a medical note-book, is a quarry, from which may be hewn the rough materials for raising on a solid basis an enlarged and systematic superstructure.

1. *Enlargement of the Prostate.*—When an old man, labouring under the misery of an enlarged prostate, says, that his water dribbles away day and night, there is reason for suspecting that his bladder is full, and already distended with one or two pints of urine, and that it is but the overflowing of the bladder that dribbles away. If a catheter be passed, it will be found to be so. But even the catheter does not empty the bladder entirely; for a certain residue of urine tarries behind in the bas-fond of the bladder; in that part of this viscus which is behind the prostate gland, and below the beak of the instrument.

The most distressing accompaniment of an enlarged prostate is the prolapsus ani, which happens in the latter stages of this complaint. The rectum becomes everted at the anus, and presents itself red and excessively tender, with a copious drainage of mucus, from the exposed surface as well as from the interior of the gut, which seems to sympathise with the neighbouring disease of the bladder. The prolapsus ani, and also piles and herniæ of the groins and thighs, result from the powerful muscular efforts which the patient makes to expel his urine. In the act of micturition, he straddles his legs, bends his body forwards, and grows red in the face; the anus descends, and the fæces sometimes escape at the same moment into the old man's clothes, while the urine drips out along the urethra, drop by drop, as hot as melted lead. At this time, blood flows into the penis, and it passes into a state of partial priapism. The patient is again and again called upon to make water, and the same efforts give rise to the same disgusting accidents, so that life becomes a loathsome burden to himself, and an offence to all who are concerned about him. The mucus from the rectum dries, and chaps the exposed surface: and, at night, the patient is disturbed by an involuntary discharge of the seminal or prostatic fluids, or perhaps by the venereal orgasm without emission,—which I have known to happen in an old man of eighty years of age. There is a constant pain of the glans penis, and along the urethra an inch from the orifice. After a time, however, the penis, the nates, and the thighs, become benumbed, and the patient only suffers from the sense of a large ball lodged in the rectum, and this ball he is always straining to expel.

In these cases, the bowels become very obstinate, and are regulated only with the greatest difficulty: soda, rhubarb, and hyoscyamus, in combination, are the most effectual. Much of the local pain and misery may be relieved by an opiate suppositary at night; but, then, opium checks the bowels, and an aperient aggravates all the evils. Dr. Heberden extols a clyster, containing tincture of opium, (see Comment. c. 75, Prost. Schirr.); and Sir A. Cooper, in his lectures, used to recommend small doses of the oxymuriate of mercury.

Beyond this, I know of no medical treatment: I have tried all things, and found them of no avail. If the patient will persevere in the use of a certain diet, and live abstemiously upon light, bland nourishment, such as milk, bread, mutton, eggs, spring water, his sufferings will be greatly mitigated; for it is the object of the patient to supply his stomach lightly, and to give his digestive organs as little work as possible to do.

Œdema of the legs, thighs, and scrotum, and an obstinate retention of urine, requiring the daily use of the catheter, forerun death: the patient becomes emaciated, suffers continual pain, and droops. The pain is not in proportion to the size of the prostate, but to the difficulty of passing the urine; and this difficulty is owing to the increased size of the third lobe, which flaps over, and perfectly stops up the origin of the urethra. Last August, I opened the body of an old man, and removed the bladder from the pelvis full of water, and not a drop escaped while I held up the distended bladder in both my hands, with the orifice of the urethra, cut off short at the prostate, hanging downwards: no urine escaped till I had slit up the bladder. The muscular fibres are enlarged, and become, on the inner surface, as visible and distinct as the carneæ columnæ of the heart: this arises from the increased exertion necessary to make the bladder contract on its contents. (See Cases of Diseased Bladder, &c. by W. Wadd, Surgeon, 1815, pl. iv.) A bundle of fibres diverging upwards from behind the prostate gland externally, is enlarged, and I have seen these fibres red and fleshy as high up as the fundus. The size of the prostate gland enlarged by disease varies; and I have found it, in one case, as large as a St. Michael orange, and, in a second, not bigger than a large walnut. It is always firm, white, and cartilaginous. Small calculi are sometimes found in the gland, and I once discovered them within the cells of the vesiculæ seminales. Just at the origin of the urethra lies the third lobe of the prostate, which in disease starts up like a crest, and at every effort at making water, flaps down on the opening of the urethra, and shuts it up. In one case which I attended, the third lobe was so situated that I had to pierce it with the catheter every time I introduced that instrument: and a long catheter was necessary. At first, I lifted up this lobe of the prostate on the beak of the instrument, and then, of

course, no urine flowed; and it was only by depressing the handle very much, and pressing it onwards, that I passed through the obstruction, and cleared the beak of the instrument, so as to let the urine flow out: on dissection, after death, I found this third lobe torn through. In another case, the patient had suffered severely for three years, and then died: the prostate was not large laterally, but the third lobe was prominent, like a pyramid. In an enlarged prostate, small whitish eminences will be found, looking at first like tubercles of the lungs: when cut into, they are white and brawny.

2. *Delirium Tremens.*—This is a madness to which drunkards are liable, when exposed suddenly to any depressing causes. A drunkard becomes feverish, with a foul tongue and loaded bowels, and while in this state he falls apoplectic, with a large, full, bounding pulse. He is bled, and recovers. Twenty-four hours afterwards he is mad; tremulous, especially as to his hands, vigilant, suspicious, sitting up, and talking incoherently of his own affairs. His skin is warm, and the breast, hands, and forehead, bedewed with large drops of perspiration. The countenance is rather pale than red, and the conjunctiva of the eye is blanched, and the pupil contracted. The eye is "physically bright and intellectually dull;" and he sees phantoms, with which he holds ideal conversations. He makes believe to be steady and rational in the presence of those whom he habitually respects, and abuses his own relations, and mistakes them for strangers and enemies. He is quite harmless, and will continue awake, wild, and wandering, for nights and days together. The pulse is very small and rapid, 130: the tongue smooth, moist, tremulous, and mottled with white. In this state, the loss of more blood, and the exhibition of more aperients, will kill him; he will grow wilder, fall into hectic, and die. But opium, in large doses, will cure him: 7, 10, 15 grains of opium, may be given in 12 hours. I have given 7 grains for one dose; and once I gave, in separate doses, at different intervals, 15 grains of gum opium, 2 drachms of tincture of opium, and 1 drachm of Battley's sedative solution, and did not relieve the patient until the end of 36 hours. The effect of opium, in these cases, is to produce a profound sleep, from which the patient awakes well, comfortable, and rational. The bowels act for themselves. The appetite returns; and meat, porter, wine, or spirits, may be allowed. Ammonia, ether, and volatile valerian, seem to be useful adjuncts; and during convalescence, the compound decoction of aloes, with ammonia, is grateful and useful.

3. *Uterine Hæmorrhage.*—Flooding may arise during any of the last six months of pregnancy, as well as during any period of labour; but I speak here of flooding in its genuine form, which, after the birth of the child, sometimes enacts a short tragedy of momentary confusion, amazement, and death. In this emergency, as in most others, presence of mind is the result of forethought; and he will be the readiest to act, who has previously taken the greatest pains to think. The knowledge how to restrain uterine hæmorrhage depends upon the knowledge of the proper action of the uterus. The child and secundines are expelled by consecutive uterine contractions; and after their expulsion, flooding is restrained by the uterus remaining contracted. If, after the birth of the child or placenta, the womb do not contract, its cavity will be filled with blood, which distends the uterus to its former size, or gushes through the vagina, or lingers partly in that passage, and coagulates. In these cases, the uterus, instead of being small and hard, is soft and full, and the blood flows; then, again, it contracts, and the bleeding ceases; and "these alternations of contraction and relaxation, with cessations and recurrences of bleeding, are familiar to the observing practitioner."—(*Gooch.*) The uterus, however, may become slowly and insidiously full, and blood will gradually escape from the stream of circulation sufficient to blanch the cheek, and to induce the usually frightful train of hæmorrhagic symptoms; and, in a delicate female, in whom this accident is most likely to happen, the uterus dilating may withdraw, and contain blood enough to cause her speedy death. Consequently it follows, that whatever will induce the womb to contract, will restrain or prevent uterine hæmorrhage; and any rule, however simple, whereby to attain

this end, will be the only rule to be observed and practised in that moment of peril.

The left hand of the practitioner, applied to the belly, ought to seek for and gently grasp and knead the uterus through the abdominal parietes, and in this manner operate upon it as a stimulus of contraction; while the right hand ought to clear out the clots from the vagina, and ascertain what is the position of the placenta within the womb, if that mass have not been as yet extruded. In cases of flooding, the left hand will not at first distinguish the uterus, which is relaxed, lost, and diffused, in the belly; but shortly, if the belly be rubbed and pressed, the uterus develops itself, firmly contracting within the grasp. If the hand on the belly discovers a circumscribed hardness, too great to be mistaken, and this circumscribed tumor is reduced to the size of a cricket-ball in the umbilical region, or below it, or on one side, we may rest assured, it is the uterus containing the placenta. Thus, the womb contracts; and the action of contraction is the action of safety. The hæmorrhage lessens as the internal bleeding surface is closed by the contracting uterus; and the physiognomical signs and gestures of hæmorrhage are changed into the look of simple faintness.

The flooding ceases, but the placenta still remains to be taken away. Most likely as the uterus was contracting the placenta descended, and now lies partly within the vagina: if so, it is quite within control, and it may be left to be pushed entirely into the vagina by the uterine efforts alone. It must not be hurried away; for as floodings are obviated only by a contracting uterus, to attempt a separation of the placenta before this contraction has ensued, would be to endanger a flooding, nay, even to rouse one. Make the uterus contract—make the uterus of itself push the placenta into the vagina; from whence it may be taken away in a moment, and at the instant pleasure of the medical attendant.

While the flooding continues, the uterus must not be emptied of its contents—the uterus must first be made to contract: follow nature; nature could not expel any thing from the uterus except by the means of uterine contraction. If the placenta still remain within the uterine cavity, he would be a foolish practitioner who would remove it suddenly during the *unnatural* relaxation of the uterus. So that, during labour, during the expulsion of the secundines, and during a certain period subsequent to birth, active contractility is the attribute of a healthy uterus.

Much has been written and advised concerning the application of cold, and of pressure and bandages over the belly. As an adjuvant, cold suddenly applied with a shock is potent and efficient: the support and diminution of the relaxed abdominal cavity may be accomplished by bandages. But bandages and cold are only secondary means: the practitioner who has the sagacity to apply and exert his hands, will often dispense with the necessity of either the one or the other. When much is to be dispatched in the shortest possible time, he will be the most useful man who can do the most with the readiest and fewest means.

It is impossible to provide against all possible contingencies. In a diseased uterus, its organic contractility might be obstructed or deranged; and emergencies may arise, when the practitioner will have to exert the vigour of his own judgment, and to rely at once upon the ready talent of the passing moment. No situation is so responsible as the care of a case of desperate flooding, especially after the birth of the child; for uterine hæmorrhage is so peremptory, that, though it would be wise and satisfactory to act in concert with another man, yet it allows time scarcely for thought, much less for consultation. Success of action depends upon habitual knowledge and mental promptitude.

Velpeau, who seems to rely too much upon revulsives, refrigerants, and the tampon or plug, speaks with much gravity of a cold key down the back, or a mustard cataplasm between the shoulders, in cases of active uterine hæmorrhage; and he seems to forget here what he calls the organism of the uterus, a matter of the highest importance, involving in its consideration some of the first principles of physiology. It can be only on physiological principles that the management of flooding can ever be rightly pursued; and the sensible man will reject forthwith the idle parade of rubbing the hypogastrium with eau de Cologne, cauterising the uterine vessels, injecting astringent fluids into the uterus, or, lastly, checking the flow of

blood into the uterus by pressing with the thumbs upon the abdominal aorta. Nevertheless I submit to the instruction of Velpeau, from whose pages I have derived a large store of useful information. (See Velpeau, Traité des Accouchmens, Paris, 1829, tom. ii. pp. 613, 615, 901.) The best stimulant to be made use of, when other stimulants fail, is the introduction of the hand into the uterus, which acts at once as a tourniquet and plug, and as a means infallible, unless the woman be moribund, of rousing the organic contractility of the womb. Upon this subject consult Gooch, Diseases Peculiar to Women, chap. v.

No rational method of cure, or even of mere attendance upon the sick, can be adopted, unless we previously understand the locality and mode of diseased action; and diseased action will present many phenomena, quite inexplicable to the man who is not acquainted with the physiology and relative anatomy of the parts when in their condition of health. Sound practice consists in a knowledge of first principles, which in medicine, as in all other affairs, simplifies, facilitates, fortifies, expedites the conduct of every matter.

Your obedient servant,
JAMES ANSLEY HINGESTON.

" DRY BELLY-ACHE" OF THE WEST INDIES.

To the Editor of the Medical Gazette.

SIR,

THE interesting paper on the poisonous properties of the salts of lead, by Dr. Anthony Todd Thomson, in your No. of the 1st of September, recalled to my mind a subject which interested me very much about two years ago—viz. the saturnine origin of the disease called dry belly-ache in the West India islands.

This still appears very imperfectly known to the medical practitioners residing there, though it is of very common occurrence, proving fatal in many instances, and in others followed by paralysis of the hands and feet. In a conversation which I had about the time above specified, with an intelligent Creole gentleman, who had himself suffered severely with the complaint, I inquired minutely into the whole process of grinding the canes, boiling the sugar, preparing the wash from which the rum is afterwards distilled, as well as into the structure and materials of all the different utensils made use of in these several processes, in none of which could I discover any probable admixture of lead. The large tanks, on which the inhabitants of the towns wholly depend for a supply of water, are formed of cement made of lime and sand, which in themselves are perfectly harmless; but when I further learnt it was the custom in the towns (to which the disease is in a great measure confined) to paint frequently the roofs of the houses, which are entirely constructed of wood, I at once discovered satisfactorily, at least to myself, the source from whence the carbonate of lead is supplied, which Dr. Thomson has proved to be more deleterious than any other preparation of this metal. The vertical sun of these climates speedily destroys the composition of the oil-paint, rendering it dry and friable, while the turpentine in the wood throws off considerable portions of it, almost as soon as it is put on. These detached portions are carried, by the first heavy rain that follows, into the tanks, for it is exclusively from the eaves of these painted roofs that the tanks are filled, and there they accumulate from year to year, yielding a sufficient supply of the poisonous matter to account satisfactorily for the prevalence of this malady, more especially when the water is low from a long drought. While on this subject, I will offer a few more observations on some of the peculiarities of this disease, which I made during the seventeen years I was physician to St. Thomas's Hospital, where there was a constant succession of patients labouring under cholic, from the extensive lead manufactories on the water-side, between Blackfriars and London bridges. The greater susceptibility of some individuals to be affected by this poison than others, was frequently exemplified by men suffering an attack of it after working only a very few days in those places, while others resisted the same exposure for ten or even twenty years. I have invariably found that, when a person has once experienced an attack, he becomes liable to relapses almost immediately after returning to the same deleterious work. I once had a patient

whose hands were paralytic solely from rubbing bougies with the tips of his fingers, and who, after recovering entirely the use of them, lost it again after he resumed his former occupation.

In the treatment of this disease I have seldom, if ever, had recourse to any other medicine than sulphur, with or without senna confection, and opium at the commencement, to allay the severity of the spasmodic pains. I was led to this practice by some observations made by Dr. Hope, in his chemical lectures, while I was a student in Edinburgh. The learned Professor, in explaining the chemical agencies of sulphuretted hydrogen on the salts of lead, recommended the use of sulphur in this disease upon theoretical grounds, if I remember rightly, rather than from positive experience of its beneficial effects. From the success which has attended this practice, I am led to recommend it in preference to any other.

A gentleman whose hands had long been paralytic, from frequent attacks of this disease in the West Indies, recovered the use of them by a six weeks' course of Harrowgate waters, taken internally and in baths.—I remain, sir,

Your obedient humble servant,

THOMAS TURNER.

31, Curzon-Street, Oct 8, 1832.

TREATMENT OF CHRONIC HYDROCEPHALUS BY PUNCTURE.

To the Editor of the Medical Gazette.

Aberdeen, Oct. 8. 1832.

SIR,

IN giving insertion to the following remarks, you will much oblige, sir,

Your obedient servant,

R. C. RUSSEL.

The employment of tapping, as a remedy in hydrocephalus, was long since suggested; but it is only lately that the practice has been attempted. Notwithstanding the success which has attended the few trials that have been made, several writers seem so averse to it as to prohibit its employment in every case as dangerous and useless. That it is accompanied with danger, I will not deny; but that it is in every case useless, I will not admit. There are cases in which I conceive it is likely to effect a cure, as, for instance, in those where the disease is confined to the membranes, which occasionally exists in the chronic forms of hydrocephalus. Dr. Bright, in his hospital reports, observes: "The apparent success which has attended one or two cases, holds out a slight encouragement to a more extensive trial of this doubtful remedy. There is no doubt that many cases will fail, for in some the tendency to pour out fluid continues unabated, and between each successive operation the head rapidly increases; but if, fortunately, as sometimes in the operation of paracentesis of the abdomen, the tendency to accumulation should have ceased, either from the effects of remedies, or from some local change depending on the abstraction, and if the cerebral disorganization should not be totally irreparable, a cure may be effected."

When the substance of the brain is diseased, no reasonable hopes of relief, I should think, could be entertained; and as it is a matter of considerable difficulty to discriminate these different diseased states, I think it may be laid down as a rule, that in no case ought the operation to be attempted when the functions of the body are much disturbed, as in such a case we may suspect the cerebral disease to be extensive and irreparable. In recommending the employment of tapping, I do not mean that it should supersede the employment of other remedies; but after they have been tried and found ineffectual. In such cases I think the ventricles ought to be punctured, as the presence of water in them will be almost invariably found. It is of little consequence which of the lateral ventricles is punctured, as the free communication which generally exists between them allows the water to be discharged from either. In evacuating the water, I perceive that, in many instances, it has not been permitted to pass in a continued stream, from fear that a sudden abstraction might prove fatal. In a case which I operated on, the water was permitted to flow in a full and continued stream, employing, at the same time, pressure on the head, and without producing any inconvenience. The period for operating, I think, should be before the time of teething, and before the bones of the head are firmly united.

PLACENTAL CIRCULATION.

To the Editor of the Medical Gazette.

The Manchester Theatre of Anatomy and Medicine, 6, Marsden-Street, October 18, 1832.

Sir,

At the last weekly meeting of the Students' Medical Society belonging to this school, held October 11th, at which I presided, the subject for the evening's discussion was—"What is the connexion subsisting between the maternal and fœtal circulations?" As this topic is now exciting much interest among our students, the discussion was very animated, and the opinions expressed, as might be expected, were various. The object of my communication, however, is not to give you the opinions of the Society on this important point, but for the purpose of describing briefly certain injected preparations which were exhibited on the occasion, obtained from the museum of the school. These preparations, which are beautifully put up, were made by Mr. Fawdington several years ago, and, consequently, not with any reference to the dispute now pending between Dr. Lee and his opponents. In order that your readers may more readily understand my description of the preparations, I may be allowed to preface it with the following remarks. The Hunters' opinion respecting the placental circulation, it is well known, was this: that the placenta is composed of two parts, a fœtal and a maternal, and that each of these parts has its own system of arteries and veins. Consequently, that the blood passing from the fœtus to the placenta by the umbilical arteries, returns by the umbilical vein; and the blood of the mother sent by the uterine arteries, is collected again in cells which constitute the commencement of large veins, and thus returns to the maternal system. In opposition to this universally received opinion of the Hunters, Dr. Lee contends that the uterine surface of the placenta—*i. e.* the surface which adheres to the uterus—is covered by a decidua, which membrane is consequently interposed between the uterus and the placenta; that on cautiously separating the placenta from the uterus, many *very small*, but no *large*, vessels are seen to pass from the one to the other through the decidua; and that with regard to there being cells in the placenta from which veins are alleged to take their origin, no such cells are to be detected. Further, Dr. Lee contends, that at that part of the uterine surface to which the placenta has been adherent, there are a number of openings passing obliquely into the uterus, and large enough to admit the point of the little finger; that the edges of these openings are smooth, and have no appearance as if they had been lacerated by the removal of the placenta; that over these openings the placenta, covered by the membrana decidua, closely adheres and seals them, so that the blood in the uterine sinuses cannot possibly pass into the substance of the placenta.

The preparations (four in number) to which I allude, appear, as far as they go, to corroborate the views of Dr. Lee, and to be altogether incompatible with the Hunterian notion.

I shall give them numerically, as they stand and are described in the catalogue of the museum, merely premising that the first was put up in 1828, and the three others in 1829.

"No. 133. *Section of the Uterus and Placenta, minutely injected from the Funis.*—The vascular connexion between the two is manifest; not only by the existence of demonstrable vessels, but also by the presence of the injection in the uterine sinuses which are purposely displayed in the preparation. It does not appear that the placenta contains cells, or any impenetrable separation between the fœtal and maternal portions, if any such exist; as its substance is *uniformly* reddened by the injection which was introduced through the umbilical artery. It seems probable, therefore, that the internal portion of the uterine parietes, cellulous decidedly as it is, has proved a source of error; the line of demarcation between the external placental surface and the internal corresponding aspect of the uterus not having been sufficiently observed, perhaps, by former anatomists. The preparation distinctly shows vessels of small calibre filled with injection passing from the placenta to the uterus, or rather to its investing decidua. The woman died in consequence of disease of the brain, about the seventh month of pregnancy.

"No. 134. *Another Specimen of Uterus and Placenta similarly injected*, exhibiting the fact of vascular continuity between these structures. The woman

committed suicide during the progress of her labour.

"No. 135. *A portion of the same Uterus.*—The cells were inflated, and the part afterwards dried and preserved in spirit of turpentine, to show that the capillaries of the uterine parietes are also minutely injected.

"No. 136. *The deciduous membrane of the same uterus, injected from the same source, and reflected.*—The vascularity of the inner surface of the uterus, where the decidua is detached, is clearly shown; and few preparations better display, as injected, the arborescent arrangement of capillary vessels than may be observed in the decidua, which is here, in part, undisturbed from its connexion with the uterus."

On inquiry, I find that the injection used, in each instance, was coloured size. I may add, also, that the uterine and spermatic arteries of the uterus, from which the three latter preparations were made, were found completely occupied with the injection.

Any further explanation respecting these preparations, which your readers may require, will be furnished with pleasure.—I am, sir,

Your obedient servant,
GEORGE SHAW, M.D.

ANALYSES OF SIXTEEN REPORTS ON CHOLERA.

Transmitted to us by the Central Board of Health.

MR. CURTIS, of Camden Town, (Sept. 25.) Is surgeon to the Police; has had 142 cases of diarrhœa; in no instance has collapse come on; attributes this, in great measure, to the men being obliged to see their medical attendant, if incapacitated for duty by illness even for one hour. Gives two table-spoonsful every four hours of the following mixture:—

℞ Mistur. Cathartic. ℥j. Aquæ Puræ ℥v. Acid. Hydrocyan. ♏xx. M.

The cathartic mixture is made thus:—

℞ Rad. Jalapæ ℥j. Magnesiæ Sulphat. lb.j. Aquæ, lb. ij. M. et decoque ad lb.ij.

If purging continues on the second day, the prussic acid is exhibited without the aperient. Makes no difference in the treatment, whether the evacuations be bilious or rice-water.

MESSRS. SHUTER and GREENWOOD, of St. John's, Southwark, (Sept. 25.) In the state of simple diarrhœa have found rhubarb and magnesia; chalk, aromatic confection, and opium, "answer exceedingly well;" speak highly of catechu in the form of tincture; have only had one case pass from this stage into collapse. (Numbers not mentioned). During rice-water evacuations, give opium, belladonna, cordials, weak brandy and water. The average of eight out of ten have recovered. In collapse, first object is to arrest vomiting: this done by means of opium or belladonna, in doses of one grain every half hour; these followed by warmth, frictions, &c. If cramps violent, occasional injections of warm water, with a drachm of laudanum, and a like quantity of spirit. ammoniæ fœtid. Of 20 cases of collapse, only 3 recovered.

MR. NIGHTINGALL, of Liverpool Fever Hospital, (Sept. 17.) In bilious diarrhœa, opiates, aromatics, chalk; alterative doses of mercury. In rice-water evacuations, the saline treatment, with calomel and opium; opiate enemata, with minute doses of sulphate of copper; copious diluents. Premises bleeding, and in many cases with decided advantage. In collapse, saline treatment, with stimulants, &c; but has little to say in favour of any thing. Venous injections failed. No numbers stated.

MR. PEARSON, of Liverpool (Sept. 25), makes little distinction between bilious diarrhœa and rice-water evacuations. Trusts to solid opium given "in proportionable quantities," and repeated "at different intervals of time;" blisters to stomach, stupes to abdomen, &c. Saline mixture, tinct. catechu comp. Small quantities of fluid at a time. Has seen "some hundred" cases; "cannot say he has lost one;" adding the following qualifications—that he has been called in in time—that his directions have been attended to, and that he has himself visited the patients.

MR. TRIGG, of Flint (Sept. 25). In bilious diarrhœa, &c. an emetic of sulphate of copper, followed by rhubarb and magnesia in peppermint-water. In rice-water evacuations, calomel and

opium (grs. v. to xv. of former, gr. i. to gr. iss. of latter); afterwards continued in much smaller doses, till the evacuations are tinged with bile. In collapse, adopts venesection "even when the pulse is imperceptible;" presses out the blood with his fingers; thinks this facilitates re-action. Frequently bleeds in the con-cecutive fever; finds the blood to be much buffed and cupped. Follows up the bleeding by calomel and opium; plaisters of mustard and vinegar to the stomach; warm-bath and frictions when cramps are severe. Has had 107 cases of "malignant cholera," including himself, wife, three sons, three daughters, and a nephew—31 deaths. Mortality occurred chiefly at first, and under the stimulating treatment.

Mr. Genis, Jun., of Ashburton (Sept. 29). Trusts to large doses of calomel, (in one case gave 180 grains in 24 hour); as soon as bile flows, patient is convalescent. Gives a scruple of calomel every quarter of an hour, till vomiting stops; afterwards, two grains, with a minute proportion of opium, every half hour, or every hour. Where bilious vomiting supervenes on the use of mercury, finds "decided advantage" from a full dose of diluted sulphuric acid.

Mr. Thomas Eder, of Liverpool. In bilious diarrhœa, calomel and opium, or equal parts of Dover's powder and hydrar. cum creta, followed by ol. ricini, or magnesia and rhubarb, &c. In rice-water evacuations — calomel, ℈j.; if cramps and pain, adds ℥ss. of laudanum; sometimes gtt. xx. of essence of peppermint. Often bleeds to ℥x. or ℥xx. Leaves a dose similar to above to be given if necessary. Does not think well of stimulants. Sometimes allows effervescing draughts, or Dr. Stevens's powders. In collapse, continues calomel, with little or no opium. Has seen hot-air bath useful, especially soon after bleeding. Has seen six recoveries from, and sixteen deaths in, collapse.

Mr. Welchman, of Ensham (Sept. 28). In first stage, has found the greatest benefit from bleeding and warm-bath, and, when not attended with sickness, ℥iss. of magnesia, in mint-water, every four hours. In second stage, two grains of calomel, with a fourth of a grain of opium, every half hour or hour. In the third stage, calomel and opium, with salines in a state of effervescence, and cold water *ad libitum*.—No numbers mentioned.

Mr. J. M'Nichol, of Inverary (Sept. 22). In first stage, calomel and opium, followed by rhubarb and magnesia; afterwards chalk mixture, with small doses of Dover's powder. In second stage, if vomiting, the patient made to drink plentifully of warm water, and afterwards ten grai s of calomel with a grain of opium given, and repeated in six hours if necessary; ℥ss. of carbonate of soda every two hours; friction with mercurial liniment over liver and abdomen, till mouth became affected. Starch injections with laudanum; heat frictions and mustard poultices to extremities, &c.; temperature of apartment kept about 78 deg. of Far. In third stage, perseverance in the above treatment, stimulants and tonics added—viz. brandy and water; quinine; aromatic sulphuric acid! carbonate of soda!! copious enemata with warm water, with a few drops of laudanum—if constipation came on, purgative clysters; if congestion about the head or liver, leeches; diet light; drink barley-water, or toast-water, sparingly. Twenty-six cases; sixteen recoveries;—eight having been in collapse.

Mr. Hickin, of Gomal, Staffordshire, (Sept. 29), after some preliminary remarks, chiefly in reference to the more advanced period of the disease, proceeds to recommend bleeding, "however late we may be called in;" to which other remedies are deemed but secondary;—one drop of croton oil, calomel, salines. Where there are rice-water evacuations without pain, chalk mixture, or the decoct. cort. granat. (℥j. to ℥ss. or ℥x.) with or without opium. If, after evacuations are arrested, there be any uneasiness at stomach, recommends an emetic of ipecac. or tartarized antimony, ℈j., in four doses—one every quarter of an hour till it operates. This emetic is also recommended in the bilious diarrhœa, followed by chalk mixture and twenty drops of laudanum. Numbers not given.

Dr. Young, of Kensington-Lane, Vauxhall, (Oct. 8.) In bilious diarrhœa, calomel gr. ij. opium gr. j. followed by rhubarb and magnesia, and after-

wards by chalk mixture, with a little laudanum. Cases "very numerous;" all terminated favourably. Rice-water evacuations have been so much associated with collapse, that can scarcely consider them separately. Trusts to calomel and opium (gr. iij. of former, gr. ¼ of latter,) about every hour. Ammonia in a state of effervescence. In decided collapse, the above, with the moderate use of stimuli; mustard poultices; and warm injections. Bleeding tried without benefit; and saline treatment, in three cases, with the same result.

Dr. Bullen, of Cork, (Sept. 27,) has treated about 1400 cases of cholera. In first stage gives an emetic (perhaps tartarized antimony,) encouraging the vomiting by means of abundance of warm water: after this, a glass of warm brandy and water, followed up some hours after by a purgative. If after vomiting, pain or cramp continues, bleeding to xvi. or xx. ounces, and a large dose of calomel; if cramps particularly severe, an enema, with two ounces of Ol. Terebinth. If the symptoms be of a colicky nature, with severe pain and spasm along the transverse arch of colon, a drachm of tartar emetic in a pint of warm water, administered as an enema, is highly praised, producing feculent motions within half an hour. Laxatives must be continued for some days. Brandy and laudanum, on the onset of the symptoms, particularly injurious.

In the second stage (in which that of collapse seems to be included by Dr. Bullen,) calomel—the great remedy; must be given in scruple doses, the first combined with a grain of opium; repeated in two hours with half a grain; and, if any improvement takes place, continued in diminished doses. Artificial heat, but not pushed too far: extensive application of external stimulants "eminently beneficial." Stimulants to be used, but with caution. "Many patients cry out incessantly for cold water, and have never appeared to suffer from indulging them with it." Turpentine and tartar emetic the best enemata in cramp and colic; but a starch clyster, with a drachm of laudanum, if serous fluid be draining away insensibly.

Mr. Rance, 4, City-Road, (Sept. 29. —In bilious diarrhœa, calomel and opium, followed by a dose of rhubarb, &c. invariably successful. Has found the malignant disease confined to a particular district, bounded on the east by Bunhill-Row, west by Goswell-Street, south by Chiswell-Street, Barbican, and Beech-Street, and on the north by Old-Street. First case occurred 25th Feb. in a woman in St. Luke's parish, a nurse of the Lying-in ward, who had not been out of the house for two months: no source of contagion to be traced. Four days after the above, two men were seized, in neither of whom contagion could be traced. Fifty-five cases under the writer's immediate care, and has seen upwards of a hundred others, in almost all of which the evacuations were nearly destitute of bile. Has found opium of use in allaying spasmodic action: has almost invariably given it in combination with calomel, but has been deterred from repeating it on account of tendency to apoplexy. Prefers mustard as an emetic, and externally as a cataplasm. Tried bleeding, but relinquished it from its inefficiency. The hot air bath disappointed him; prefers tins filled with warm water. Used hot brandy and water at first, but found it to be injurious. Writes of the saline treatment as follows:—

"The last remedy for cholera that I shall notice is the saline, as recommended by Dr. Stevens: our attention was directed to its use by the reported success of the cases at the House of Correction for the County of Middlesex. The salutary effects at the first administration were not equal to the extent we had anticipated. Since our personal interviews with the Doctor he has kindly furnished us with more minute particulars of his plan. Dr. Cambridge, (the medical gentleman appointed by our local Board of Health to the care of the cholera patients of this parish,) with myself, have seen in a large number of cases its exhibition attended with the happiest result, not only in the rice-water evacuations, but also in the stage of collapse. From what I have witnessed, it is but justice to Dr. Stevens to acknowledge that I place more reliance upon the saline treatment than on any other that has as yet been recommended."

Thinks favourably of venous injection; has tried it five times: two recoveries.

Dr. Pennick, of Penzance, (Oct. 2.)—

Has seen 76 cases; 9 deaths, 65 recoveries, 2 remaining. Attributes several of the deaths to destitution. Tried bleeding from the head, by dividing the sealp, in two cases; both died. Employed mercurial fumigation in twelve cases; eight recovered. "With regard to what has been called the saline treatment (says the writer) I must remark that trial of it has not enabled me to discover its advantages." Has applied mustard poultices to the abdomen, covered them with several folds of flannel, laid a thin board over this, and a firm calico roller over all. When the cataplasm is taken off, the other parts of the swathing reapplied as before: "the result has been most satisfactory." Generally commences with a small bleeding. If stomach loaded, an emetic of ipecacuanha: opiate enemata. In one case, where reaction followed collapse, there was much determination to the head, stomach, and mammæ. An old woman sucked the breasts repeatedly, and suffered no inconvenience. In another case, where the patient's child was put to the breast, it was taken ill next day, and died. Conjectures the different result to have depended on this—that the old woman spat the milk out, whereas the babe swallowed it.

Mr. W. Collyns, of Kentor, near Exeter, (Oct. 3.)—At any period anterior to collapse, an emetic of mustard, salt, or ipecacuanha, and an aperient of rhubarb, gr. x., sulphate of potass, one drachm to a drachm and a half, aromat. confect. gr. x., and T. opii, gtt. x. If stomach would not retain this, effervescing draughts, with ammonia; afterwards, pulv. kino comp.

In vomiting and purging of watery fluids, an ounce of common salt in a tumbler of hot water, as an emetic; then a tea-spoonful of salt in a tumbler of cold water, to be drank *ad libitum;* saline effervescents; lime-water and milk; toast and water; solution of isinglass, with 20 or 30 drops of laudanum, as an enema. Very large quantities of the above beverages were taken and rejected by some—3 or 4 gallons of a night; "but (says the writer) I found those who drank most salt and water began to have a yellowish tinge of bile in the evacuations sooner than the others." Thought the lime-water (two parts with one of boiled milk) did good, particularly in children. The liniment hydrar. fortius assiduously used. Recovery began when gums became sore. During the collapse, external heat and mustard cataplasms employed: free ventilation of great use. All stimulants hurried on the stage of collapse.

Mr. G. Dickens, of Hertford, (Sept. 28.)—In first stage of diarrhœa, tincture of rhubarb 3ij. in compound tincture of senna 3vi.; to be followed in half an hour by a table-spoonful, after each liquid evacuation, of a mixture containing infus. catechu, with a little tincture of cinnamon, and a drachm of laudanum, in six ounces. If there was vomiting, 3ss. of ipecacuanha, followed by catechu mixture, as above. In the more advanced stage, gives the compound soda powders (sodæ carb. gr. xxv. ammoniæ carbon. gr. x. pulv. cornu ust. c. opio gr. x. M.) every hour, "which (says Mr. D.) I have almost invariably found to answer every expectation;" generally continues them for four or five hours; after which he exhibits a scruple of calomel, with ten grains of pil. cornu ust. c. opio. Lastly, gives bitter tonics, to promote convalescence.

RECENT VARIATIONS IN THE TYPE OF CHOLERA.

To the Secretary of the Central Board of Health.

Cork, Sept. 18, 1832.

Sir,

I perceive by the periodicals that the Central Board of Health are anxious to obtain every information respecting the various modes of treatment adopted by the physicians who have had charge of the Cholera Hospitals. Enclosed is a pamphlet I published in the month of May, after having treated about three hundred patients.* Since that time I have had under my care more than eleven hundred cases of malignant cholera, and the result of my further experience has been to confirm, in every respect, the opinions expressed in the pamphlet. When the epidemic first appeared in Cork, a number of cases were accompanied by colicky symptoms, which we have not seen at all during the later months. In these, bloodletting was extremely beneficial; but we now seldom or never can have recourse to it. The number of persons attacked at pre-

* See preceding page.

sent is comparatively few, but the type of the disease is infinitely more malignant than at first. Cramps are no longer a prominent symptom; the quantity of the serous discharge, whether by vomiting or purging, is comparatively trifling; and the patients die with no other symptoms than coldness of the body, clammy sweats, and extreme anhelation. For some weeks, in the North Cholera Hospital, all the fatal cases have terminated in coma; the type of the disease has thus appeared to have undergone a change, and the patients sunk, passing bloody stools in quantity. After a short period, these leading symptoms would again become of rarer occurrence, and the cases would terminate in profuse and uncontrollable vomiting and serous diarrhœa. In every variety, the treatment must be modified; but whilst I found calomel always indicated, opium required the greatest care in its administration. The neutral salts, bichloride of mercury, croton oil, &c. have all been tried, and laid aside.—I am, sir,

Your obedient servant,

DENIS B. BULLEN, M.D.

3, Grand Parade.

ANALYSES & NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

A Practical Treatise on Cholera, as it has appeared in various parts of the Metropolis. By CHARLES GASELEE, M.R.C.S. Surgeon to the Marshalsea Prison, and ALEXANDER TWEEDIE, M.R.C.S Resident Medical Officer to the City of London Cholera Hospital, in Abchurch-Lane.

AMID the host of productions of all sorts and sizes, relating to cholera, which are daily, and we may say hourly, claiming our notice, we have selected the one at the head of this article, as different in some essential particulars from most others. It is written to support no new theory and to recommend no treatment, old or new, as specific and infallible. The authors have seen much of cholera, and it is evident that they have seen it with observing minds. All the different methods which have been adduced with any respectable claims to attention, they have tried fully, and it appears to us fairly; looking upon the subject without the partiality with which the proposer of a novelty may be supposed to contemplate his progeny, but also without the jealousy of those who have some offspring of their own to countenance and support. We have already had occasion to publish some of Mr. Tweedie's opinions, in the form of original communications to this journal, and an abstract of a report, by Mr. Gaselee, in our last; from the brochure before us we shall therefore content ourselves with making two selections—the first relating to contagion, the second to the experience of the authors as to different plans of treatment.

"*Contagion.*—If, by these terms [viz. contagion and infection], either, or both, be meant the power of one body labouring under disease to generate a specific poison, which can communicate to, or cause the same specific disease to arise in another, we simply state our conviction that the bodies of patients labouring under cholera are possessed of such a power, and that, consequently, the disease is contagious or infectious: but to expect to be always able to detect the operation of such an agent in cholera, is as unreasonable (particularly when the air is contaminated by a poison) as to look for the source whence a person may have contracted the virus or morbid impression which has induced other diseases acknowledged to be contagious, with the expectation of invariably finding it. Neither do we admit the propriety of the term "contingent contagion," which we believe to be supported by a species of paralogism, to which all sound argument is opposed. If by it be meant that an entirely new property is superadded to a disease by external agents, we deny the position 'in toto;' if it means that the disease is contagious under certain circumstances, we cannot admit it as a term of distinction, because all diseases may be said to be so, inasmuch as they do not always shew that they have such a property: 'for in infection and contagion from body to body, as the plague, and the like, the infection is received many times by the body passive; but yet is, by the strength and good disposition thereof, repulsed*.'

* Bacon.

Cow-pox virus is contagious, under the circumstance of its being *inoculated* into a body capable of receiving its influence. Small-pox virus does not ordinarily affect those who have been fortified by the vaccine action, because the natural property is counteracted by a superior power, but the property is not, on such an account, the less inherent in small-pox virus. The real explanation of these things we believe to be, that external or certain circumstances have the power either of developing, counteracting, or mitigating, the naturally inherent contagious qualities of a disease, but we must again pause before we admit their power of generating a property entirely new. We know not what other meaning to attach to the term, and look upon the epithet 'contingent' as superfluous, and 'contingent contagion' as paradoxical. The notion of the doctrine of contagion being disheartening or injurious in its operations, is from an erroneous view of its bearing, and a total misapprehension of its principle; and to arraign a doctrine as unchristian in its effects, appears to us to be a censure on him who ordained it. The error lies with those who misunderstand its nature, and from it form wrong deductions, and does not rest with *the* doctrine or its supporters; and if we could choose between such a disease as cholera being contagious or otherwise, we believe that a right view would lead us to prefer that it should be the former. These remarks may appear, at first sight, speculative; but will be found, on examination, to have a practical tendency."

"1st. *Large doses of Calomel.*—To the plan of administering very large doses of calomel, such as ten or twenty grains every hour during collapse, we have this objection—it is altogether unnecessary, and sometimes succeeded by bad effects. To calomel itself, in more reasonable doses, we have no objection, as may be gathered from the purport of our former remarks. Every useful purpose that mercury can be expected to accomplish is realized by the more moderate doses, but the effect of the larger quantities is to promote an inordinate excretion of bile, *unmixed with fæces*—to excite irritation of the intestinal mucous membrane—to bring on frequently bloody stools—and to terminate the case either by relapse into collapse or by a severe attack of gastric fever; such, at least, has been the result of those cases in which we have pursued this plan of treatment.

"2dly. *Venous Injection.*—We have tried this in twelve cases, and the event has been twelve deaths: all these case were, it is true, apparently moribund when the operation was performed. We have varied the method of performing it; in some instances injecting only a few ounces, in others, as many pints; and though the immediate effect in most of them was to bring on, as it were, a resuscitation to life, yet was the termination of all alike. Some relapsed into collapse, and died rapidly; some had difficulty of breathing induced, which contra-indicated its repetition, and others died with symptoms of cerebral oppression. In one of these last examples, on examination after death, we detected effusion on the brain, and within its ventricles, of a fluid, very similar in taste, appearance, and alkaline reaction, to that which had been injected into the vein. We have found the blood in the bodies of such persons just as black as in those who had died without this medication.

"The injection of warm water alone produced the same re-action as that of the saline solutions, from which we are led to infer that this method of treatment acts only as a mechanical, and not as a specific stimulant; but since we know that it has succeeded in the hands of others, and that it is a remedy applicable only to otherwise hopeless cases, we see no reason to despair, that in the progress of improvement new and satisfactory data will be elicited, which shall enable us to discriminate, without empyricism, the conditions under which it may be rendered available as a remedial agent.

"3d. *The Saline Treatment.*—The result of our trial of this treatment is as follows:—

"Treated upon salines up to the period of their termination, 16; recovered, 1; died, 15.

"Salines at first, and when collapse was not averted by them, or when they disagreed, other means adopted, 6; recovered, 4; died, 2.

"A mixed saline treatment, other remedies being given at the same time, 8; died, 8."

THE ROMANCE OF CHOLERA*.

A Tale founded upon Fact.

WHAT a subject for a tale to interest the public! "The Cholera Morbus at Paris" an article in the "Book of the Hundred and One." We know, to be sure, what Boccaccio made of the plague of Florence, and our own Defoe of that of London: but is not M. Bazin a little too hasty? Cholera still rages in the French provinces; nor is Paris entirely free from it: yet here it is already dressed up into a story for the popular palate. The novelists of Italy and England waited awhile, to allow time to throw its romantic and cloudy veil over the dismal occurrences which they undertook to record: but the Frenchman cannot afford to wait; he has his quota to contribute to the bookseller's fund—and he lays hold on the pestilence, to work it up, after his own fashion, and for his own object. And a French dish he has certainly made of it. We know not whether M. Bazin is a professional man or not—but we should suppose not—we are almost sure of it—from the internal evidence which his performance affords: this, however, may be a *ruse* of his authorship. In his account—which we must allow to be a very amusing one—he does not enter of course on the pathological phenomena of the disease, from the perusal of which he knows the public would willingly be excused, but he describes the general effects which its sudden presence produced in a population which it nearly decimated. He presents us, moreover, with a picture of manners at once so characteristic and so lively—and, we believe we may add, so true, that he stands a good chance of being hereafter reputed as the veritable historian of the period. Defoe has more than once been quoted as good and grave authority—and why may not M. Bazin? A French editor, we may observe, has already spoken strongly in favour of his productions. "Our monographs on cholera," says the *Gazette Médicale*, "will be imperfect, unless they include this piece, by way of appendix, to complete the history of the disease." On this side the Channel, however, we rather fear that the style of M. Bazin will not entitle him to our unlimited confidence. We shall present the reader with a few passages. We take a specimen from our author's opening paragraph. What can be more historico-poetical?

"It was on one of those beautiful but perfidious days of spring, when the rays of a prematurely hot sun boil up our blood, and then expose us, palpitating under their influence, to the chill of evening: a time fertile in rheums, catarrhs, quinzies, and checked perspirations. It was, moreover, a sort of festive time; for we had not yet spent the day which relaxes the austerities of Lent. The mass of the population was poured out on the boulevards, eager to see, or rather to have seen, the secular drollery which the children salute with the old cry of the carnival. All was gaiety, and bustling, and dust; no municipal guard—for the police have nothing to do with this joyous period—every one may amuse himself at his own risk and peril. Thirty or forty merry masquers might be seen amid the crowd, anxious to catch attention, and to attract personal notice, which was plentifully bestowed upon them with the witty compliments of their admirers. The weather was enchanting, but there was blowing a harsh wind from the north—a wind that was calculated to give a sudden blight to the tender flowers of the almond tree. It was then—it was in the midst of a multitude full of mirth, and laughter, and gay discourse, and boisterous enjoyment—that a frightful report was first circulated amid the throng. Luckily it was the *Moniteur* that spread it: it came with an official air, and there was time to doubt of its veracity."

This report was the news of the arrival of the cholera, which set all the speculators on the *qui vive* to find out how it could possibly have come. The positive people held that it could not have come; but the government had promised to take every precaution; and the positive people were dying with fear. Things were worse the next day, when the proclamations were published bidding the people to be calm. Cholera was now perceived in every thing: it was smelt in the sepulchral gas of chlorine, which was universally employed; it was felt in the flannel drawers, and flannel every thing that was put on; it was heard every where; in short, it was seen in the ladies' faces. "It was a bad sign," says the author, "when the women took fright."

"It was pitiable to see those lips, from which the charming words of consolation and hope used formerly to flow, now frozen

* Le Livre des Cent et Un. Tome v. Paris 1832.

with terror and shrivelled with camphor: those figures pale and ghastly: eyes sunk and haggard: foreheads yesterday smooth and fair as polished ivory, to-day wrinkled with the incessant snuffling up of a volatile salt or essence: no longer to inhale near a pretty woman, her balmy breath and the perfume of her hair; but, instead, an abominable odour of pharmacy!"

This was certainly most shocking.

The author then proceeds to bewail the revolution in culinary matters, the interdiction laid upon good-living, and the total desertion of the cooks' shops. The time hung heavily on the hands of the whole French population: "our days," says M. Bazin, "were long and weary—*bien tristes*; our nights—*sans amour et sans sommeil*" (!)

"In the morning, the journals were turned over with fear and trembling; it was not politics that was looked for; nobody cared for the Chambers, the telegraphic despatches, or the results of diplomacy. A new insurrection, if such a thing could have been got up, would have found no sympathy. The cypher—the terrible and growing cypher of deaths—was the all-engrossing object of public attention."

The state of the public streets, too, was calculated to spread alarm; not that there were fewer people moving about than usual, but wherever you went you were sure to meet *coffins*; if you happened to turn round, you saw a man in black, who was walking behind you and carrying on his shoulders the last purchase for some rich man or the last alms for a pauper—in short, a wooden suit which seemed just your own fit! Then you beheld abundance of hearses and mourning-coaches, with their long black palls, and those strange funeral Omnibuses, now for the first time made familiar to the eye, bringing their numerous passengers home to their last abode. But what was most striking, you probably fell in with a party of stout labouring people who either could not wait for, or could not afford to use, the ordinary conveyance, and were carrying a corpse in their arms, with a sheet simply thrown over it: this you could not avoid allowing to pass—you involuntarily paid it a tribute of respect by standing still; yet it might be all a smuggled affair—a subject for the novelist or for the prosecutor!

"Business, however, was by no means at a stand; and every morning brought its new bills of fare for the pleasures of the day. The shops were all open as usual—the restaurateurs had their ovens hot—the cafés merely added mint and *tilleul* to their ordinary beverages—the fiacres rolled about town—the citizens mounted guard—the journals were full of discussions and news as ever; justice pursued her steady course; the Bourse had its movements of rising and falling, and the political world its hopes and its miscalculations. There was rioting, too, for a time, about the first few days of the epidemic, as if to add to its severity. Paris, in fact, seemed to have given up none of its customary practices, saving one—that of *marriage*: nobody seemed sufficiently assured of his life, body, or estate, to be willing to connect them with those of another. In every other respect people were as industrious as usual—as if not to let their hands out of practice. I have been assured, though I will not vouch for the fact, that a novel (*un Roman*) was published at this time. But the theatres were, perhaps, the scene of the greatest calmness and courage; their doors were thrown open night after night, and, in presence of a semblance of a public who were probably more regardful of their bowels than of the business of the stage, the poor actors, themselves disturbed in their bowels (*inquiets eux-mêmes de leur entrailles*), or blighted in their affections, came forward to play their mimic parts—to grimace gaiety—or to put on sorrows other than those which they really felt. The proprietors, we know, had their losses made good to them: that was as it should be; but surely the actors deserved civic crowns for their noble conduct, if those who ran from their posts had but the generosity to reward them who remained firm at their benches."

There is but one passage more with which we shall trouble the reader; and it is one which we feel too gratifying to our professional pride to allow it to pass silently by.

"But if civic crowns were to be disposed of, the medical profession should have of them amply. The pestilence is not far enough from us yet, that we should begin anew to banter medical science. If the art has been weaker than the evil—if it has proved uncertain—if it has stumbled—if it is still in doubt, after a long and painful experience—the zeal, at least, of the artists has been immense, heroic, admirable. In the bold struggle with a murderous foe, let it not be forgotten that beside the victims there were martyrs. The profession have been courteous too: they suffered the severity of the disorder to pass over before any *doctrines* were pro-

posed before any discussions were broached; *they never disputed by the bedside of the dying.* There each did his best, whatever were his principles; and the excellence of each method was shewn in the numbers which it saved. Let us not, then, unkindly notice their differences, lest they, in their turn, should begin to speak of our alarms and our weaknesses—of the fancies which they had to humour, and the terrors which they had to appease—nay, of the rude health which they were often called in to cure!"

M. Bazin is really very polite to the faculty—notwithstanding his hits in italics. We vote that he be himself entitled—to one of his own civic crowns.

MEDICAL GAZETTE.

Saturday, October 20, 1832.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

MEDICAL REFORM—EDUCATION.

In no other part of the world does the medical profession hold so high and honourable a rank as in this country: here it truly deserves the title of a *liberal* profession: no where else can such a beadroll of distinguished names be exhibited:—

"Great men have been among us: hands that penned
And tongues that uttered wisdom, better none."

But there are those among us now who would have the profession liberal in quite another sense of the word—and would make it permanently so, by beginning at the root. There is abroad the cry of a party clamorous—not for the reforming, but for the revolutionizing the whole state of the medical commonwealth. These liberals, however, are luckily not a numerous party—not near so numerous, at least, as they would have the world believe: nor is their object any thing more than to try the fortune of an experiment—to make a bold push at whatever hazard to others; for themselves, they have nothing to lose, while they have every thing to hope for from the issue of their adventure. They proceed plausibly: they advocate the doctrines of unbounded freedom, free trade, free *grade*, free—every thing! They preach against the professional corporate bodies, not so much on account of those circumstances in which they are really exceptionable, as on account of the obstacle which their power and influence present to the adoption of their own wild and Utopian innovations. Education is the grand theme on which they found their complaints—and this they promise to remodel altogether: they will make it *free*—there shall be no restraint upon genius; no forms to curb the ambition of rising merit; expenses shall be but a mere trifle; and examination the sole test of qualification. Few, we should hope, if any, are the dupes of these malcontents; yet, lest any there should be, we will take the opportunity of considering what would be the consequences of this same *liberal* system of education—if system that may be called, where system there is none. It might, indeed, render further allusion to the schemes of these wholesale subverters of educational discipline unnecessary, were we to examine the pretensions of each of them individually, whether they themselves ever enjoyed, so as to understand the value of, those departments of medical education, the regular acquaintance with which they look upon as so useless. But though such an exposure were easy, it is notoriously unnecessary, and could not well be made without being more personal than we desire: we shall, therefore, confine ourselves to the fruits of the plan proposed—for by their fruits may the producers best be known.

Only let us fancy the attendance of all the classes in our medical schools

made optional, and then let us inquire how many pupils would attend? how many schools would remain open? May we not fairly judge from the attendance on those classes which have hitherto been optional? And, with regard to the schools, may we not form an idea from the number of them that existed previous to the regulations under the Act of 1815? The number of general practitioners who have passed the Court of Examiners of the Apothecaries' Society, and are now exercising their functions all through the land, are calculated at about 12,000; and so many, at least, are required for the wants of the population: how many of these would be the competent persons they are but for the Society's regulations? No doubt the number, and perhaps five times the number, would be distributed, in *practice*, throughout the country: but in knowledge, unlike physics, numbers are not strength—neither is there a talisman in a mere name. What a state of things would it be, were the barriers removed, and the entrance to our profession left carelessly open!—the irruption of the Gothic hordes upon the civilized world, were but a type of the plunder and blood which must ensue. Medical callings would revert to what they were in times gone by, when every desperado and person of broken fortunes might think himself qualified, or at least entitled, to practise medicine, as a last resource. Then, indeed, adieu to all attempt at control,—or even to that which the semblance of an examination would afford! Examinations! who would be the Examiners? Who would be the accessaries before the fact to incalculable slaughters?

Such is a sample of the levellers, or rather the annihilators, of all medical education: but, in the wildness of their schemes, is found the best security against them. There is, however, another class, proposing to themselves the same general object—a reform in the system of education—which may be distinguished and characterized by their choosing the French for their *beau ideal*. "They manage these things better in France," is the alpha and omega of their argument, as still they prate of the anatomical arrangements,—the inscriptions,—and, above all, the concours. Now, as the first party that we have above described, by their hot-brained intemperance, overdo and mar the very plot which they desire to carry into effect, and stand in the way of all reform by the extravagance of their pretensions; so neither are the present class much better calculated to advance their cause. They forget the very latitude in which they live—they overlook the existence of a whole system intrinsically dissimilar—they allow nothing for national peculiarities—or, with a complete ignorance of human nature, they would attempt to drown them. Granting that the French system works well—a fact which might be made serious matter of question—what is there, in the whole history of the profession in England, that can induce these people to believe that the introduction of Gallican arrangements could possibly tend to improve us? Our educational machinery, such as it has been—such as it is, has produced, and is producing, a race of practitioners of which no nation in the world need be ashamed; the natural inference from which would be, that if our system be not absolutely the best that can be devised, it is, at least, essentially and in principle, the best for us: not that, in saying so, we are not fully sensible that certain improvements are required, of which we shall more particularly treat anon; but what we maintain is, that all such improvements and alterations must be made in the spirit of the national character, and in accordance with the feelings and principles still cherished in this country.

Those who advocate sweeping changes borrowed from foreign institutions, we are disposed to believe can scarcely be aware of the nature and extent of what they propose; nay, we suspect that they would themselves be among the first to find fault with them, were they once introduced among us. Of the French system, generally, it may be sufficient to remind the reader, that it exists under the regulation of a species of martial law: the government has a voice—and a voice potential — in the nomination of every teacher; and the whole *Ecole de Médecine* may be regarded as an engine of state, the most minute portions of the machinery of which are committed to the surveillance of police officers. Hence the close connexion of political changes with the repeated alterations in the medical establishments of that country: hence the frequently disturbed condition of the Parisian students, carrying the violent and factious conduct of political partisans into the theatres of the schools: and hence, we may add, the frequent presence of *gens d'armerie* in the saloons, for more than a guard of *honour* to the professors. How far would the admirers of our Gallic neighbours go?—would any of these latter arrangements be suited to their tastes?—would they prefer seeing our lectures attended by military—as we have seen Cuvier, during a whole course, address his audience having a sentinel, with fixed bayonet, mounted beside his chair?

Of the concours, and certain other peculiarities in the French form of medical *regime*, we have, on several occasions, expressed our opinions freely: and how well those opinions were founded, later events have shown. The concours, after having been clamorously demanded, and obtained, after the "three glorious days," almost as the first-fruits of the second revolution, has already, after numerous changes and chances, and abortive attempts to get it up to the summit of imaginary perfection, fallen into a state of ridicule and contempt, like the cast-off bauble of some spoiled child. The unsatisfactory and unsettled condition of the Parisian school of late, must give pain to every observer; while it amply demonstrates that it contains little or nothing that we should desire to make our own.

The liberality of the German school is of a more congenial sort. With less pretension, it possesses in it more of the elements of real utility—more to admire and to imitate, than can be found in the French institutions. The excellent method of clinical instruction, which has been brought so conspicuously before the public, in a paper published by Dr. Graves in this journal, is confessedly of German origin and German growth.* But it would be to anticipate some of our observations on the subject in hand, to notice this topic at present more particularly.

From some of the preceding remarks, it may obviously, and not improperly, be inferred, that we are no advocates of optional education—and that we put no faith whatever in the principle, that the knowledge requisite for entering into the profession will be obtained, either in degree or kind, by the unregulated student. We admit that there are and have been exceptions: but rules must be adapted for the mass, and not for the individual,—or, as the old maxim has it, *leges fiunt de his quæ vulgo, non de his quæ raro, eveniunt.* Our impression is, that nothing should be left to mere recommendation; nothing deserves to be recommended that ought not to be insisted on; and if the recommending party have not the power to insist upon what they recommend, they may as well save themselves the trouble of merely

* Some valuable remarks on clinical instruction, were made by Dr. Latham, in a lecture which he delivered a few days ago, at St. Bartholomew's—we shall give them a place in our next number.—E. G.

suggesting that which the natural freedom characteristic of the English student prompts him to disregard. And why, may we ask, in the first place, why is so all-important a step as the preliminary one of a classical and scientific education — left to mere chance, by one, at least, of our regulating bodies? Is there any thing, perhaps in the whole *curriculum*, framed and disposed for the student's use, so necessary as that this groundwork should be strictly and strongly secured? that the mental discipline, inculcated by a liberal education, should be positively insisted on—as the best, if not the only, preparative for a successful prosecution of medical study, and as, subsequently, the most trust-worthy passport to that rank in society which the practitioner of medicine should hold? The absence of such a regulation we conceive to be a fundamental imperfection; nor can we promise ever to contemplate any code of educational rules, with satisfaction, while such a hiatus is staring us in the face.

If we still keep to fundamentals, we pass from the essential groundwork of the arts to the elements of professional knowledge — the study of anatomy. Much, we are aware, has been done in this department of late, and much, we are sure, will continue to be done, as the clouds of popular prejudice pass away under the influence of the new enactment. But there is one step that ought to be taken in time—and the sooner the better, for the sake of our anatomical character: the measure we allude to is the necessary one of establishing courses of a fitting length. Nobody will misunderstand us on this head: our protest is directed against the inconceivably absurd regulation of countenancing *three months'* courses. Who that has ever handled a scalpel and forceps has not been at once convinced of its absurdity? and yet as a *regulation* it has continued to disfigure the codes of our corporations even unto this day. The same arrangement, (we are almost ashamed to recollect) has existed with regard to the theory and practice of physic! How will this look hereafter? Surely no better than an injunction of a three months' course of Chinese.

Here, for the present, we must break off; but it is with the intention of returning to the subject.

THE RESURRECTIONISTS.

Some of those desperate men who heretofore have lived by the plunder of the grave, have been endeavouring, in various ways, to annoy and disturb the anatomical teachers in the metropolis. In some instances they have endeavoured to create disturbance, with a view of extorting money — in others, they have tried to obtain employment at their old occupation, offering to furnish "subjects" for two pounds each, instead of twelve, the average price of last year. Thinking the temptation would prove too strong to be resisted, a party of them last week went one night to several schools with two bodies, offering them for any thing or nothing: at last they pressed one gentleman for heaven's sake to take the bodies, were it only to bury them, for they were fearful of being detected, as no one would give them admission. We can confidently state, that the determination peremptorily to decline all connexion with these men, has not been deviated from in a single instance, and thus the public has been the first to gain by the new act; for the temptation to rob the grave ceases with the possibility of disposing of the plunder, and thus may the friends of the deceased feel assured that their "*requiescat in pace*" will not be in vain—that hereafter the grave will, indeed, be sacred.

WINE FROM POTATOES.

M. Jacob, an old army officer, having an estate at Forges on the Meuse, has occupied himself in endeavouring to make wine from potatoes; and, after many ingenious experiments, has at length obtained a liquor like Muscadel. He confidently anticipates producing other varieties, and constituting a new and important article of commerce.

EXTRACTS FROM JOURNALS,

Foreign and Domestic.

INCREASED POPULATION OF AUSTRIA.

The number of births in Austria during the years 1828-29-30, amounted to 2,275,532, and the deaths to 1,928,434; so that during the three years above mentioned, the increase in the population was 347,098. The greatest increase took place in the maritime provinces, and in Dalmatia, Bohemia, Moravia. On the other hand, in Lombardy, Styria, Venice, and Carinthia, there has been no change.—*Gazette Médicale.*

EXCORIATED NIPPLES.

Pyroligneous acid, mixed with white of egg, is stated, by Dr. Burshardt, to be an excellent application to excoriations of the nipple; even when attended with great irritability.—*Ibid.*

ARRESTING HÆMORRHAGE.

Dr. Arentz, of Norway, recommends nitric acid as the most powerful means of arresting hæmorrhage. In bleeding from a vessel too deeply seated to be easily accessible, or in false aneurism, he pours eight or ten drops of nitric acid into the wound.—*Casper Critisches Repertor*, t. 30. c. I.

FECUNDITY OF HYOSCYAMUS.

According to some experiments, the hyoscyamus produces more than 50,000 seeds; but assume the number to be only 10,000, the seeds would amount at a fourth crop to 10,000,000,000,000,000; and as the quantity of solid land on the surface of the globe is calculated to be about 1,400,350,599,014,400 square feet, it follows, that each square foot must contain seven plants, and therefore the whole earth would be insufficient to contain the produce of a single hyoscyamus at the end of the fourth year.—*Penny Magazine.*

COMPARATIVE PRODUCTIVENESS OF CERTAIN VEGETABLES.

A spot, of a little more than a thousand square feet, will contain from twenty to forty banana plants. A cluster of bananas, produced on a single plant, often contains from one hundred and sixty to one hundred and eighty fruits, and weighs from seventy to eighty pounds. But on reckoning the weight of a cluster only at forty pounds, such a plantation would produce more than four thousand pounds of nutritive substance. M. Humboldt calculates, that as thirty-three pounds of wheat, and ninety-nine pounds of potatoes, require the same space as that in which four thousand pounds of bananas are grown, the produce of bananas is, consequently, to that of wheat as 133, and to that of potatoes 44·1.—*Ibid.*

CLINICAL REPORTS FROM THE HOTEL DIEU, PARIS.

CASES AND OBSERVATIONS ON CERTAIN FORMS OF GANGRENE,

By M. Dupuytren.

Arteritis:—Coagulation of the Blood—Symptomatic Gangrene—Death.

A woman named Sigolet, 40 years of age, and of regular habits, was admitted into the Hôtel Dieu, July 15, 1832, for incipient gangrene of the right leg. She was of delicate constitution, but had always enjoyed good health, with the exception of having recently suffered from cramp in the right lower extremity. She had dull pain, of but little severity, which was first experienced in the right iliac region; from this it descended along the inner part of the thigh, and then to the back part of the leg, till it reached the sole of the foot and toes. These parts were affected with prickings and acute shooting, which passed into fixed burning pain. It was only then, being about eight or ten days before her admission into the hospital, that the foot began to grow cold: purple spots appeared, and the pain became so great as to prevent sleep.

On his visit of the 16th, M. Dupuytren found that the foot and leg of the right side were swollen to twice their natural size as far as the knee: the skin was tense and shining, as in phlegmonous erysipelas. The foot was of a deep purple towards the toes, which became less intense a little farther up, and shewed itself in marbled patches on the leg. The cuticle was removed at some points. The part was extremely cold at the upper third of the leg, and this continued increasing down to the toes: the sensibility was diminished in the

direct ratio of the heat; the power of motion still remained entire,—a circumstance easily understood, when it is considered that most of the muscles of the foot are situated on the leg, and chiefly at its upper third. The pulsation of the femoral arteries of the left side was felt to be full and regular, while in the right one the pulsations were so extremely weak as to be almost imperceptible: the artery seemed to be converted throughout its whole extent into a hard and nearly incompressible cord. The diagnosis made by M. Dupuytren was—"arteritis, of which the gangrene is but a symptom." The patient was ordered to lose three paletts of blood, to have a large poultice applied to the limb, and slop diet.

The bleeding had the effect of alleviating the pain and indueing sleep. It was repeated next day, and on the 18th its effects were still more marked: the pain was nearly gone, there was less swelling, and both the heat and sensibility had returned at several points. On the other hand, the mortified part was covered with vesicles containing dark fluid, which bursting, discovered the cutis, black, gangrenous, and fœtid. The limb was enveloped in camphorated spirits.

On the 22d she was bled for the third time. For some days after, the gangrene appeared to be arrested about four fingers breadth below the knee: it was supposed that the whole thickness of the limb beneath was mortified. The movements of the foot were now entirely lost, but the leg could be bent on the thigh. Nevertheless, whether the nerves had resisted the sloughing, or whether it was from a phenomenon analogous to that which takes place after amputation, the patient still occasionally experienced exquisite pain in the foot. Up to this time the treatment had not overcome the diseased process, but yet it had appeared to be retarded. However, about the end of July, notwithstanding two more bleedings, the icy coldness pervaded the knee, and progressively extended upwards. By the 11th of August the mortification implicated the lower part of the knee-pan, the coldness being well marked two inches higher up, and no pulsation was now perceptible in any part of the femoral artery. On the 16th the lower third of the thigh was involved in the gangrene, and then the strength, which had hitherto held out, began to break very rapidly: diarrhœa came on, and she died on the 19th, being thirty-five days after her admission.

Autopsy.—The body and limb externally presented nothing to remark in addition to what is above described as present during life. The vessels were first examined in the part of the thigh which had remained sound, at least which was not gangrenous. About the middle of the limb the artery, though natural in appearance, was diminished in size, and contained a thread-like coagulum, of a red colour, and which was supposed to have been formed after death. Towards the crural arch the vessel regained its ordinary size: it was hard, incompressible, and filled with a clot, red on the surface, and slightly adherent to the sides of the artery; within it was of greyish colour, and appeared to be formed of fibrine. This was continued up as far as the origin of the primary iliac, and even extended a little into the left iliac, but without obliterating it. The internal iliac was also obstructed by a clot of the same kind. The right crural vein was filled with a firm red clot. The vessels of the left lower extremity, the aorta, and the heart, were all nearly empty. Between the parts which remained sound, and the gangrene, was interposed a space of from two to three inches, which had been cold during life: there the cellular texture displayed the appearance of a reddish grey and very marked capillary injection, alternated: lower down, at the margin of the gangrene, the vascularity disappeared. The skin was black, hard, and dry as parchment; the subjacent cellular tissue of a yellowish grey; the aponeuroses pale; the muscles of a bright red, moist, and streaked with layers of cellular tissue more white than natural; the nerves rose-coloured; the vessels in the ham containing a greyish clot, like that found higher up; the bones of a pale grey, with the periosteum firmly adherent.

M. Dupuytren remarked, that this constituted an excellent example of what used to be called "spontaneous mortification"—the "gangrene of old persons"—"gangrene without a known cause;" but that these appellations must now be discarded, as pathology has explained the disease. Gangrene of the extremities may take place from very different causes. In old persons ossification is generally found in the arteries of the limb, and then too the dead parts are almost always dry, and not tumefied, as in the preceding case. In other instances the evil is caused by an organic affection of the heart—a circumstance remarked by Corvisart. In adults, at an earlier period, we also sometimes meet with arterial ossification; or gangrene may result in them from ligature of the great vessels—events sufficiently well known. But a more frequent cause, and to the merit of first discovering which M. Dupuytren lays claim, is acute inflammation of the artery, with coagulation of the blood, obliteration of the vessel, and consequent complete interruption of the circulation. Formerly, reasoning from views

purely theoretical, and likening this kind of mortification to what was seen from frost-bite, it was asserted that it occurred most commonly in winter, whereas just the reverse is true, for it is particularly in the summer months that it occurs. The woman whose case is above detailed was attacked during the period of the greatest heat. M. Dupuytren it was who first pointed out this fact, and it was the circumstance of its greater frequency in summer which led him to suspect that there was some error in the old hypothesis. The above case is also curious, as exhibiting the disease in the female, (women being decidedly less liable to it than men,) and at an early period of life (10). It is remarkable, however, that M. Trioen has seen two cases in young girls, one of 23 and the other of only 9 years. At first the disease is purely local; the respiration and circulation, as well as the functions of the brain and of the alimentary canal, remain undisturbed, and it is only when the disease has made some progress—doubtless only when absorption has commenced from the putrid mass—that the general system sympathizes, and fatal consequences ensue.

The progress of the gangrene is marked by an extraordinary sense of cold and paleness of the part. It is not, as might be supposed, a reduction of temperature analogous to what takes place in the dead body, and which only happens because the corpse assumes the temperature of the surrounding medium—it is an icy coldness, and is greater than that of the dead body, nay, the thermometer sinks lower than in the air, or even than in a current of water. M. Dupuytren long since made many experiments on this point, and ascertained that the temperature of the part about to fall into this kind of gangrene became less than that of the dead body. The pulsations in the artery, as seen above, cease, or nearly so, and in the situation of the vessel a firm cord is felt. It was predicted before death that the artery would be found obstructed as high as the aorta; but in one respect the diagnosis was not complete; for though the artery was obstructed at the aorta, yet lower down the clot was a mere thread, and it was the coagulum in the vein which gave the feeling of a cord along the inner side of the thigh. During fifteen years M. Dupuytren witnessed the exclusive use of bark and similar means, which proved quite unavailing: since the cause of the disease has been better ascertained, and repeated bleeding adopted, "we have cured two-thirds, and even three-fourths, of our patients."

[The reporter asks why opium, as recommended by Pott, was not used in conjunction with the bleeding; and why, as the disease still advanced, amputation was not had recourse to, in the manner practised by Larrey—a practice which has been followed by some well-marked examples of success.]

Ascites:—Gangrene of the Foot supervening immediately after Tapping.

A woman named Bourbon, aged 56, apparently exhausted by fatigue and privation, so that she looked twenty years older, labouring under dropsy. About three months ago, the ascites having become very considerable, she had the operation of tapping performed. Immediately after, the foot swelled, and in two days, to use her own expression, it was "dead." The gangrene had reached the ankle, and the bones were separated at the articulation, and the soft parts a little higher up, the tibula and fibula projecting, and being in a state of necrosis. The patient had no pain; the arteries pulsated freely, and no ossification could be detected. The tapping required to be repeated, and was followed by no inconvenience. The belly being thus emptied, led to the detection of two hard and painful tumors within it, one to the right, the other on the left of the umbilicus, but they exhibited no pulsation, and the circulation was not disturbed.

Here was a case in which the cause of the gangrene remained unknown. M. Dupuytren expected to have found some lesion of the abdominal circulation to explain it, but was compelled to abandon this conjecture.

Peculiar Mortification of the Cellular Membrane.

M. Dupuytren afterwards made some remarks upon another form of gangrene, hitherto undescribed. We sometimes see slow inflammations, with little heat or pain, attack individuals of different age, sex, and constitution. It is a subcutaneous swelling, which takes at least two months to be developed, and which sometimes requires twelve months for this purpose. At last the skin becomes purple, fluctuation is felt, and on opening it scrofulous pus is evacuated, which discovers a slough at the bottom of the abscess. The wound is dressed in the usual way, but no progress is made, and the slough does not separate. Two or three months pass before it is detached, and then it comes away in one piece, white, hard, and excessively fetid, and appearing to be constituted entirely of cellular membrane, and yet, what is extraordinary, not becoming softened by putrefaction. After this the bottom of the wound is seen to be very unequal, partly red and partly white, and it is still a long time ere healthy granulations make their appearance. Several

cases of this kind have lately been treated in the Hôtel Dieu: in one, admitted on the 8th of August last, a very large slough of the above description separated from a chronic tumor on the right side of the thorax.

ON THE IMPORTANCE OF THE NITRATE OF SILVER IN SURGERY.

To the Editor of the Medical Gazette.

Sir,

We are very apt to be impressed by cases which occur in our own families; and such a case has forcibly brought to my mind, during the past week, how much the profession of surgery owes to Mr. Higginbottom for his Treatise on the Nitrate of Silver.

My cook wounded the back of the hand, over the tendon leading to the middle finger, very severely, by its being caught by a hook used to suspend meat in the larder. Whether this hook was merely blunt and rusted, or whether it was poisoned by animal matter, I do not pretend to say: but more frightful consequences I never beheld. In four hours the back of the hand was excessively swelled and painful; the back part of the middle and third finger was affected by extreme numb pain, and pain and redness extended up the arm.

I gave an emetic—calomel and senna. I applied the nitrate of silver deeply in the wound, and so as to induce a complete eschar of the skin, all over the painful, red, and swollen parts. The effect was magical. In two days there was no dream of danger.

I have not thought it necessary to say more on this case, my object being only to draw the attention of the profession to Mr. Higginbottom's work, in which so many similar cases are fully detailed. I cannot refrain from expressing my opinion on that work—viz. that it constitutes the most valuable addition recently made to surgery. It should be in the hands of every student.

Philalethes.

London, Oct. 12, 1832.

P.S.—The effects of the nitrate of silver are surely unaccountable. The middle joint of the middle finger was swollen and tender, from a wrench in getting out of a gig. It had been stationary for a month. The part was involved in a black eschar made by the nitrate of silver. The swelling and tenderness subsided. Before the eschar peeled off the part was well!

BITE OF THE TONGUE.

A young woman was admitted into the Hôtel Dieu last week, under the care of M. Breschet, complaining of a severe wound of the tongue. She lived, it appeared, with a man of a violent and jealous disposition, with whom she had frequent quarrels. In the midst of one of their family jars, the man suddenly seemed appeased, and offered to make it up with a tender embrace: the simple girl had soon cause to rue her consent, for the fellow seized her tongue between his teeth, and nearly severed it in two!

The pieces of tongue were put together by sutures; and the patient was reported to be going on well in the course of a few days.

Wounds of the tongue get well without much difficulty. Besides the great number of vessels which the organ posses es, and the vital activity with which it is endowed, its surface is constantly moistened with saliva, a liquid very proper for keeping the divided parts in a state favourable for cicatrization.

LECTURES

ON THE

THEORY AND PRACTICE OF MEDICINE;

Delivered at the London University,

By Dr. Elliotson.

EXANTHEMATA.

Lecture IV.—Part II.

Rubeola.

I was speaking, gentlemen, at the last lecture, of measles, but I almost forget how far we had proceeded. The general symptoms of the disease have, of course, been pointed out. I also mentioned that sometimes the measles will disappear, and then return. I think I observed that they disappear often at the same time that some internal affection occurs. Bronchitis, or some other *itis*, will come on, and as long as the internal affection lasts severely, very likely the measles will not re-appear. The internal affection may be the consequence of the measles receding, but in a great number of cases it is the internal affection that puts a stop to the progress of the disease on the surface.

Period at which there is the greatest liability to the affection.—Infants, or at least children, are thought to be much more susceptible of the disease than adults; but infants at the breast are certainly not so susceptible of it as others. It is not at all an uncommon thing to notice the disease in a family of children, all of whom have it excepting one which is at the breast. There is no doubt that extreme infancy is not so disposed to the disease as later periods of infancy: it is considered, however, that infancy at large—childhood, and the young adult period, is more subject to it than the full adult period, and much more so than old age. In considering this question, we ought to reflect on the circumstance, that although fewer adults have it than children, yet it is a disease that occurs generally but once, and it is possible that the reason why it is not seen in adults is, because almost all adults have had it when children. That may be the reason. To ascertain the fact fully, we ought to have a number of adults who never had the disease, and expose them with an equal number of children who never had the disease, and see how many of each are affected, and if a smaller number of adults still escaped than of children, even that might not be satisfactory, because those adults probably did not have the disease in infancy, from a positive indisposition, and that indisposition might still prevent them from taking it. We can draw no inference from the number of persons who have the disease in childhood, which is usually the case. Dr. Babington, I have heard say, has seen measles occur after sixty years of age; and it is a fact that we may see small-pox after seventy, and some children are said to have been born with measles, and others with small-pox, and others have had it at a very short period after birth; but, as a general rule, the extremes of age are very unfavourable to this affection.

The longer the premonitory symptoms occur, and the general indisposition before the appearance of the eruption, and the more severe they are, generally speaking the more severe is the disease itself. The affection, too, is usually more severe in the cold than in the warm months. Sometimes, in the severe form of the disease, there are about the fourth day small dark patches in the mouth (the mucous membrane being affected as well as the skin,) on the hard and soft palate, upon the tonsils, and upon the uvula.

Exciting cause—Inoculation.—The exciting cause of the disease is indisputably a peculiar

contagion, and this has been communicated by art—the disease has been conveyed by inoculation. Experiments of this kind were made many years ago by Dr. Hume, the father of the present professor, and himself professor of materia medica in Edinburgh. You will find his experiments related in a work of his, called Clinical Facts and Experiments, published in 1758. Many have thought but little of these experiments, but in 1822 an Italian physician, Dr. Speranza, in the territory of Mantua, repeated them. He inoculated six cases, and afterwards himself, with the blood taken from a slight scratch in a vivid papula. In a few days the measles appeared, and went through their course mildly and regularly. This encouraged him to make further experiments, and he says they were all successful. Occasionally the measles do produce little vesicles, and it is certainly likely that these vesicles do contain the contagion itself in a concentrated form. Many who have attempted to inoculate for measles have failed; but that measles have been communicated by inoculation, there can be no doubt; and as the disease, when produced naturally, is so severe, and that produced artificially is so slight, and most children have the disease, I almost think it a pity that the subject has not been more attended to. There is not the same facility of producing this disease as small-pox, but it appears a possible thing to communicate it, and there can be no harm in scratching a few children, and attempting to give them the measles during the favourable period of the year; and I do not see why, as most children have it, they should not be exposed to the contagion, by having the clothes of others labouring under measles placed near them, during the warm summer months.

No indemnity from a second attack, unless there be catarrhal symptoms. — The measles are sometimes said to take place on the skin, without any internal affection, without any catarrhal symptoms, without running of the eyes or nose, without sneezing, heaviness of the head, or cough, and it is said that when the disease occurs in this exceedingly mild form, it does not prevent a second attack. This was mentioned by Dr. Willan, and, as an accurate observer, he was perhaps never surpassed; but Rayer will have it that this kind of disease is not measles at all, but only roscola, that simple slight blush of the skin that I formerly shewed you. Dr. Willan, however, says, that he saw two distinct cases of measles — indisputable measles, without any catarrh; and I myself attended a family, in whom several of the children had had the measles, with catarrh, and one of them had, at the same time, an eruption exactly like the others, and which was pronounced by the medical attendant to be the measles. The rest of the family never had the disease again, but this one, a year afterwards, had regular measles. From this fact, occurring within my own knowledge, I cannot but think that Willan is right. If any one could distinguish between rubeola and roscola, it must have been Dr. Willan. Besides, all contagious diseases will occur in an imperfect form. The most intense contagious disease may be of unusual shortness, or of unusual mildness, or both, and even want some of its symptoms. Small-pox pustules sometimes occur with no indisposition. Doubtless, measles is no exception to the general truth. When small-pox has so appeared, Willan says it may begin regularly and perfectly on the eighth or ninth day from the first appearance of the pustules, *without indisposition*. Measles, again, in the same manner, will appear, and proceed perfectly sometimes in a few days after the eruption, *without catarrh*.

Lividness not a dangerous symptom. — The measles are sometimes attended with a darkness of the skin; the rash suddenly becomes yellow, or livid, about the seventh or eighth day; there is languor and quickness of the pulse, but no inconvenience arises, and the whole ceases in a week or two. It does not appear that there is any danger from the mere lividness of the patches in this disease. Many eruptions of the skin, when they subside, become of a dingy or yellow colour, and without any danger whatever; there is merely a little change of colour, independent of the present indisposition. So it happens in measles; the dinginess is more intense than usual, the part becomes exceedingly brown and yellow; but this generally ceases after a week or two. Perhaps the blood is in a state approaching to stagnation, the circulation not going on in the natural way. This is called *rubeola nigra*.

Putrid Measles. — But it is said that measles sometimes do occur really in a typhoid state of the body; that putrid measles do take place. Sir William Watson, who was physician to the Foundling, said that he saw this 60 years ago in that hospital, but others think it was an error, because like Morton, a cotemporary of Sydenham, he did not distinguish measles from scarlatina, and proposed to banish the latter word as superfluous. Indeed the original writers on measles all consider it and small-pox as the same disease in different forms. However, Dr. A. T. Thomson declares that he saw a case in 1804, where the languor and state of the pulse were alarming, and the skin rubbed off like a moist cobweb, but the patient recovered by

the use of wine and cordials. I never saw this form, but the other is not exceedingly uncommon.

In plate xx. you will see a representation of measles without catarrh, which is said not to give impunity from the disease afterwards; still I see nothing peculiar in the eruption. You observe that there are patches of a semicircular form. If a child have measles without catarrhal symptoms, it is well to tell the parents that it may have an attack again. If you do not adopt this method, the family will say, "Mr. so and so said the child had the measles, but it never had, or it would not have them now:" it is therefore well to save your character. A second attack of measles is possible under any circumstances, but if they occur without catarrh, it is almost certain that the patient will have them again. In plate xxi. there is a representation of the dark coloured measles, which Willan calls *R. nigra*.

Period of Incubation.—In regard to the time at which the disease occurs after exposure, Willan says that he knew a person who had had the measles and become convalescent, and his clothes infected a child in the country, and that child had the eruption 16 days after being first exposed. I suppose the usual period is from five days to a fortnight, but most probably there is variety, as in most other contagious diseases.

Treatment.—In regard to the treatment of measles, the first point is, I stated, to attend to any internal symptoms of inflammation that may exist. A large number of cases will do very well without any medicine at all. The child cannot eat, and therefore, if not recommended by the parent, it will not take any thing to do it harm. It is more inclined to take plain water, milk, or milk and water, than any thing else. It is right that the patient should be kept cool, but it is rather dangerous to keep it cold. It should be kept in a moderate, but by no means in a stimulating temperature, for heat would do great harm, and aggravate any disposition to bronchitis; but I do not know that there would be the same propriety in exposing the child to cold air that there is in small-pox and scarlet fever; there is such a disposition to bronchitis. I do not think it would be right to bleed generally or locally, to prevent bronchitis; it is time enough to do so when it begins. If the child be young, the moment there are symptoms of an inflammatory affection of the chest you should apply leeches, but if the child be old, you should bleed from the jugular vein or the arm. There is nothing more easy than to take blood from the jugular vein, unless the child be too fat. The treatment should be that of bronchitis. If the disease continue, you must look out for local inflammation, and if that local inflammation cause the eruption to disappear, and you can subdue it, then the eruption will return. The warm bath will be useful, and it can do no harm. Scarcely any affection occurs in a child in which the warm bath is not of use.

The diarrhœa after measles is generally of an inflammatory character, and is best treated by the application of blisters, or a sinapism if the child be too young for a blister; but blisters are very dangerous things to employ in the case of very young children; I should prefer the application of a sinapism, because it is taken off in a moment, and great external irritation is quickly produced, and may be regulated at pleasure. However, it is not improper to give astringents in the diarrhœa that follows measles, but you must look out for local inflammation, and if that exist you must combine the astringents with the proper remedies for inflammation, or employ the remedies of inflammation only. Measles are very apt to leave after them an obstinate diarrhœa, which ends in disease of the mesenteric glands, and a bronchitis that is apt to leave a disposition to the formation of tubercles. You have chronic bronchitis, and then tubercles, so that children frequently die of phthisis; but measles often set up scrofula both in the abdomen and chest.

I need not say, that in the putrid form of measles, which I have never witnessed, the opposite plan must be adopted, only we must take care not to mistake a blackness from bronchitis from extreme congestion in the lungs, for a putrescent state of the body. When there is congestion of the head and chest, wine and tonics would be exceedingly improper; but I should think that a careful practitioner would not make the mistake to which I have adverted.

Scarlatina.

The next disease among the rashes, of which I will speak, is scarlet fever, which is called, in medical Latin, *scarlatina*.

Formerly confounded with Measles.—This disease was confounded with measles till the close of the eighteenth century. Morton, who was a cotemporary of Sydenham, as I have just told you, thought they were mere varieties of the same disease. In the middle of the seventeenth century, Sennertus asks why the disease is sometimes small-pox and sometimes measles? and Diemerbroeck, who published in 1687, asserts that measles and small-pox differ only in degree. Such were those days of diagnosis. In 1769, Sir William Watson did not distinguish measles from scarlet fever. On this account, you heard, some have affirmed that Sir William did not

see the putrid form of measles; that what he saw was putrid scarlet fever, and that, as he did not distinguish between the two affections, he called it measles. Indeed Morton, who confounded the disease, wished the word scarlet fever to be banished altogether. He conceived that the two diseases, measles and scarlet fever, were but one, and he thought it a pity to use both words, —that the term measles was quite sufficient to designate the whole disease. Bateman thinks that 1793 was perhaps the first year in which an accurate diagnosis was made. Dr. Withering published an Essay on Scarlet Fever in 1788, the second edition of which appeared in 1793; and Dr. Bateman considers that the latter was perhaps the accurate date of the first correct division of these diseases. This must appear to us strange, now that the diagnosis is established between the two diseases with the most perfect facility; but so it is, and I trust that those who live a hundred years after us will be satisfied that we were an ignorant set—that science will so advance, that hereafter our knowledge will appear perfect ignorance. You see that at the present moment people cannot settle how long cholera has existed—whether it is a new disease or an old one. Some say that it sprung up a few years ago, and others assert that it has been known from time immemorial. It is just the same with scarlet fever: some say that it was not known more than two hundred years ago; that it is not mentioned in the Arabian, not to say the Greek, writers; and that it came from Africa, and broke out in Europe for the first time in Spain, in 1610. Willan says it was known to the Neapolitans before 1500, under the name of *rossalia*, or *rossallia*, and that Ingrassia describes it under that name; that others called it *rosalia*, *robelia*, *rubiola*, *rubeola*, *rubeolæ*, *rubeoli*, (from *robia*, madder, and measles, *morbilli*;) and that the French used all these words for scarlatina, and even *rugeole*, terming measles *senession*. The word scarlatina was formerly scarlattina, and derived from *scarlatta*, a red-coloured cloth.

Symptoms.—This disease is characterised by a close and diffuse efflorescence of the skin, of a high scarlet colour, and affecting likewise the mouth and fauces. There are the usual symptoms of pyrexia for about two days, and in some part, the second day generally of the pyrexia, the eruptions appear. In the greater number of cases I believe this is true, but occasionally the eruption will not take place till the third, fourth, fifth, or sixth day; and when the eruption does take place, it continues about five days.

Causes.—Scarlet fever arises solely from contagion. I use the word contagion in a generic sense. It is a disease that usually occurs but once during life; but I believe the exceptions to this rule are more frequent than the exceptions to small-pox. Small-pox occurs twice more frequently than measles, and I believe scarlet fever occurs twice more frequently than small-pox; but I am not certain, for some persons do not make a sufficiently accurate diagnosis between such a rash as roseola and scarlet fever. Still, however, it is by no means uncommon for persons that have had scarlet fever to have a sore throat if they be exposed to the infection of an individual labouring under this disease. It is by no means unusual for those who have children about them labouring under scarlet fever, to have a sore throat characterized by intense redness; and that sore throat is sometimes very severe. Occasionally, persons who have had it formerly, or are recovering, have not only sore throat, if strongly exposed to the contagion, but even spots like flea-bites, sometimes of a dark colour. Being of this infectious nature, the disease is often epidemic; but it is more prevalent at the equinoxes than at any other period of the year.

Children most liable to the disease.—It occurs more frequently in children than in others, but the extreme of infancy is least liable to it, just as it is least liable to the measles. It differs, however, from measles and small-pox in this—that persons generally are not so liable to it. Almost every body has the small-pox, unless by chance they have had the cow-pock, and are thus prevented; but you will find a great number of persons that never had scarlet fever. It is common to find persons that never had the scarlet fever, although they have been exposed to the contagion; but it is very uncommon to find persons that have not had the small-pox, or cow-pock, and measles. I have been exposed to the scarlet fever enough, but I never had it, though of course I have had small-pox, measles, and hooping-cough, and all those things which people usually have. Dr. Willan says, that he never saw the disease occur more than once, although he had witnessed 2000 cases of it. When I was a pupil, it was denied that small-pox or measles ever occurred twice; but now that there are so many persons capable of making good observation, cases have been sufficiently multiplied to settle that point.

Period of Incubation, &c.—The period at which the disease usually takes place is three, four, or five days after exposure; but in adults the interval between exposure and the appearance of the affection is greater than in children. The disease may be caught by being near a person labouring under it, and therefore it is infectious. It may be caught, too, by touching any thing

that the individual has touched; and it may be caught from a second person. If an individual visits a person labouring under the disease, and then visits another, the second person visited may catch it from him. It may be communicated too, it is said, by the exfoliated portions of cuticle. One must conceive that these are impregnated abundantly with the perspiration, and therefore that they will communicate the disease; but I do not know myself, from observation, whether this is the case.

Character of S. simplex.—In the most simple form of the disease, that called *S. simplex*, the feverishness is very moderate. On the next day from the commencement of the feverishness, innumerable red spots appear on the face and neck, and these, in twenty-four hours, will spread all over the surface, coalescing and multiplying They thus increase and multiply, enlarging the redness, and uniting together, till they form large extensive patches over the trunk and extremities. On the third day there is almost one diffuse and continuous efflorescence over the body, and especially around the fingers. The scarlet hue is usually most vivid on the flexures of the joints, the skin there being very fine, and likewise on the loins. The patches are seldom universal on the trunk, but upon the extremities they are very continuous—run to a great length. If you turn aside the bed-clothes, you perhaps observe one continuous redness from the groin down to the foot, the patient looking almost like a boiled lobster; and towards evening the redness is so intense that the patient looks as if he had been smeared with raspberry-juice. Some lobsters are redder than others; but the colour at evening is like that of a very red lobster, or skin smeared with raspberry-juice. You may find, on passing your finger carefully over the skin, minute roughnesses—asperities exceedingly minute—far more so than you observe in measles; but you do not observe the irregularity that occurs in measles. In measles you find the whole skin raised in patches, and, besides that, you feel frequently small papulæ; but in scarlet fever you do not find the patches at all elevated—you do not find continuous elevations—but you may, with the point of the finger, discover exceedingly minute asperities. The distinction between the sensations given to the touch in the two diseases, is very obvious. In measles, as I have just said, the patches are more or less elevated, and you may feel in the midst of some of them little papulæ; but in scarlet fever you will not find the patches elevated above the rest of the skin, and, instead of finding little papulæ, you find only the most minute asperities possible, resembling the large cutis anserina, such as you find in the cold stage of ague; and it is only upon the breast and extremities that you can find these in scarlet fever.

Progress of the Disease.—It is usually upon the fourth day that the eruption is at its height. On the second it comes out; on the third it has spread all over the surface, and if the lower parts were exempt before it reaches them now, and it is at its height of redness; on the fifth it declines, and it declines by interstices, so that the patches re-appear. While the disease was increasing, the patches were lost in one continuous redness; and then, as the disease declines, the continuous redness becomes again divided into patches—that is to say, there are intervals of paleness. On the sixth day the eruption becomes very indistinct, and generally it is gone before the end of the seventh. Now and then, if the disease be severe (and sometimes when it is not), between the fourth and seventh day there are, as is observed in measles, little miliary vesicles. In acute rheumatism I have seen the fingers beset with vesicles; and the same occurrence takes place in measles, and sometimes in scarlet fever. About the eighth or ninth day the cuticle comes off in the form of scurfy desquamation.

The disease attacks the interior of the mouth and fauces, and it even affects the conjunctiva. The papillæ of the tongue become enlarged, and you may see them through the white crust with which it is loaded. The tongue looks as if it had been slightly sprinkled with Cayenne pepper. There is a dry mucus on the tongue, through which are seen peeping these red points. If there be any cough in the disease, it is not that peculiar cough which I mentioned as occurring in measles. In measles there is a peculiarly sounding cough, such as sharp women and nurses know very well to be the cough of measles, but that does not occur in scarlet fever. If there be any cough at all, it is merely a short irritating cough—a cough merely from irritation of the fauces, without any expectoration or hoarseness. From the conjunctiva being affected, there is a redness of the eyes, but no intolerance of light, and no overflowing of the tears; and the ciliary glands are not affected.

If scarlatina be at all severe, you may have discharge from the ears, both within and without—discharge from the meatus; and it may give rise to sore ears—to glandular suppurations in various parts, in the parotids and in the glands of the neck; and it may give rise to pulmonary disease and to diarrhœa; or it may be followed by chronic pustular diseases of the skin, called rupia and ecthyma, but which are much more common after small-pox. After mild scarlet fever there is very often general

dropsy — anasarca. The other symptoms which I mentioned (such as discharge from the ears, suppuration of the glands, &c.), all occur after the most severe forms of the disease, particularly that called *S. maligna*; but after the mildest form you may have dropsy. This dropsy usually occurs at the end of the second week, and after the rash declines. It occurs particularly in spring and in autumn; and, if I be not very much mistaken, it is generally owing to the patient having caught cold in some way or other.

In the plate I now shew you (xxii.) there is a representation of S. simplex, in which you observe continuous patches and asperities, or a very minute roughness in the skin.

Character of S. anginosa.—If the throat be affected in a very marked manner, the disease is called *S. anginosa*. You now and then have the disease with little or no affection of the throat; perhaps there may be a slight affection, but frequently it is so slight as to deserve no notice; but if it be very obvious, the disease is called S. anginosa. There is then more violent inflammation of the fauces, which increases and decreases with the eruption; the general disease of the system and the eruption are altogether more intense. The heat may be 106 or even 112 deg.; and there is sickness, headache, restlessness, and delirium. The throat feels sore and straightened, and on inspection a dark red line is seen, in various instances, along the velum, reaching down to the lower part of the uvula. The patient is hoarse, experiences a difficulty in swallowing, and the tongue is very red, especially at the sides and the extremity. The papillæ are particularly affected, so that they are greatly increased in length. In this more severe form of the disease, the eruption often does not appear till the third day, and very often the eruption is not so universal, but is in scattered patches, and very often it does not come out fully and remain so, but appears and disappears. The whole disease is thus lengthened; from the eruption not coming out permanently it is protracted. I mentioned that when the measles recede, when they come out and go back again, the eruption may last for some weeks. So in scarlet fever, if the disease comes and goes, then the period of the eruption is increased; although I do not know that it can be increased to the period that I have seen it in measles. When the disease thus goes off, the desquamation is less regular, and, if the rash have been slight, as it sometimes is, even when the throat is much affected, there is, perhaps, no desquamation at all. Sometimes we see exfoliations of large portions of the skin, for many weeks, and these are usually upon the hands and feet. The nails have been known to crack and separate, and now and then superficial ulceration will take place on the tonsils, and for the most part there are shreds of viscid secretion, which are mistaken sometimes for sloughs, but they are merely vitiated secretion, excessively thick portions of lymph; now and then you have real sloughs, with great debility after the disease.

Character of S. maligna.—But we have another form of the affection, in which there is a great disposition to sloughing, to mortification of the throat, and to putrescency of the body, in which there is extreme indisposition; and this is called *S. maligna*. The distinctions of this disease are very proper, but you have only to remember that there is a mild form of the disease; another in which the throat is much affected; and another where there are typhoid symptoms. With respect to scarlet fever, the names of the species are not unworthy of being remembered, as is the case in many other cutaneous affections. In this violent typhoid form of the disease, the efflorescence is dark and livid; it comes out even still later than in *S. anginosa*, where the disease is attended by an inflammatory sore throat, and it is of uncertain duration; is continually going and returning, and there is less heat of the body. In *S. anginosa*, I said the heat might be 112 degrees, but here there is less heat, and the pulse, although perhaps very quick, is languid. There is great affection of the head, great delirium or coma; in fact there is encephalitis, inflammation within the head, and sometimes there is other inflammation present. The eyes are red, and the cheeks are darkly flushed. There are sordes of the tongue and mouth, dark sloughs in the throat, the bases of which are livid; and great fœtor from the nose and mouth. There is an acrid discharge through the nostrils, which irritates the skin upon which it comes. There is diarrhœa, and frequently petechiæ, black specks on the surface of the body; hæmorrhage occurs, and death often takes place in two or three weeks. Sometimes the patient sinks suddenly within the first four days. Occasionally the disease does not shew this malignant character at first, but goes on pretty mildly, and then all at once puts on these malignant symptoms.

Morbid appearances.—When the body is inspected, there are found to be various internal congestions, inflammations, and effusions, and inflammation of the surface, not of the interior, of the skin.

It is this frightful form of the disease, which, when recovered from, leaves such severe complaints, as ulceration within the ears, chronic diarrhœa, and such diseases

of the skin as rupia and ecthyma. I do not know that this form of the disease is more frequently followed by anasarca than the others. So rare, however, is this species of the affection, comparatively, that I have never yet had occasion to treat a patient with it. It is, perhaps, a singular thing, that I never yet lost but two patients with scarlet fever; but it has solely arisen from this circumstance, that they have always been mild cases which I have treated, such cases as required cold washing, cold air; and the local application of leeches was occasionally demanded. I have heard other practitioners say that they never lost a case of scarlet fever. Luckily the disease does not put on this severe malignant form except in rare cases.

OBSERVATIONS

ON

CLINICAL MEDICINE.

A Lecture delivered at St. Bartholomew's Hospital, October 17, 1832,

By Dr. Latham.

Since the commencement of this season, I have found myself attended in the wards of the hospital by a much larger number of pupils than usual; therefore I have assembled you here to-day, that you may learn what *my* notion is of clinical instruction, and what you are to expect from me as a clinical teacher.

I have always thought that hospitals are not converted to half the good they are calculated to serve as schools of medicine and surgery; and I think so still.

I have always thought that, in hospitals, knowledge is perpetually running to waste for want of labourers to gather it; and I think so still.

I have always thought that, in our schools, every mode of lecturing has been unduly exalted above clinical lecturing; and every place where knowledge is to be had, or is supposed to be had, has been unduly preferred to the bed-side; and I continue to think thus.

With respect to clinical lecturing itself, custom has robbed it of its peculiar character, and, withal, of half its advantages, and half its popularity. It has been separated too much from the wards and the bedside, and has deviated into a discussion of abstract pathology and therapeutics. There may, indeed, be things which can be discussed with convenience and propriety only apart from the patient; and so let them be. But these bear a small proportion to the multitude of things which can only be learnt at his bedside, and in his very presence.

Here is a hospital containing 500 patients—a wonderful spectacle! Hither resort hundreds of students from every part of the empire. Here they see what the majority will never see again, after the period of their pupillage is over. They see collected in one place every variety of disease, and every variety of injury; and numerous specimens of each. What an opportunity of instruction gained, if rightly used—what an opportunity lost, if neglected!

And which is generally the case? Is the opportunity, in fact, generally used or neglected? I speak from my own certain conviction, and I answer that it is generally neglected. I know that five out of six of those who profess to attend the medical and surgical practice of this hospital (and it is the same at other hospitals), never watch a single case of disease, either medical or surgical, through its entire course, during the whole period of their pupillage. I say this with great sorrow, and as a warning to those whose pupillage has yet to begin. This is what I mean by the materials of knowledge running to waste.

Now, seeing among the students of our profession that zeal, that hunger and thirst after knowledge, which I do, I must be slow to charge upon them a systematic disregard of things most essential. May I presume rather to suspect that the discipline they are subjected to is a little faulty? I should be sorry to prejudice students against the course of instruction laid down for them—I would rather urge them to greater diligence, that so they might overcome any little impediments which lie in their way—nevertheless, my situation of physician to this great hospital having given me some insight into the system of instruction pursued, and convinced me that it does not work so well as it ought, it becomes my duty to point out where I think the machinery labours.

I think, then, considering the limited period which the majority of students can devote to their education, a great deal too much is required from them as preparatory to their becoming practitioners. Among the multiplicity of things which they must bring certificates of having learnt, there is a fear that they learn some very imperfectly, and some they do not learn at all; and there is a chance that what they thus learn imperfectly, or not at all, may be the very things concerning which it is most important that they should be competently informed. And such is really the fact. So pressing upon the student's mind and time is the neces-

sity of attending a multiplicity of lectures, that he has neither attention nor leisure left to bestow upon the observation of diseases and the effects of remedies.

But how are you to abridge the catalogue of lectures, and what is there now taught which you could fairly exclude, in order to make way for a more ample observation of disease in the wards of hospitals?

Anatomy must be learnt: the form, the situation, the structure of parts, must be known; even their intimate healthy structure should be much and often examined, by the medical student especially, that his eye may become skilled in detecting deviations from that structure, and tracing the visible vestiges of disease. Dissection, too, must be practised, by the surgical student especially, that his hand may be accustomed to the ready use of the knife. All the time that is bestowed upon it is therefore fairly due to anatomy.

Then come chemistry and the materia medica. And let no man who is making his entrance into the medical profession henceforth ever neglect chemistry. Chemistry was once thought to be conversant only with the physiology of external nature; but every day is bringing us to look more and more to chemistry to explain the physiology of our own bodies. It cannot, therefore, be suffered to become a less prominent part of medical education than it is. The same may be said of the materia medica. The articles of the materia medica are not likely, upon the whole, to increase in number; but those in use will require a more accurate study; more will be known concerning them, and more will consequently be to be learnt. Besides the natural history of many vegetables, there is also their chemical analysis. Chemistry has already detected, in several, the simple principle to which the whole plant is indebted for its medicinal virtue; and these simple principles are beginning to be largely and beneficially employed in practice. This, then, is not a time to abridge the study of the materia medica, when science is making in it new discoveries every day, and drawing from it more powerful and more convenient agents.

Then there are lectures upon botany—lectures upon midwifery, and upon the diseases of women and children—lectures upon forensic medicine. Now I dare not say that the subject matter of all these lectures is not of the highest order; and therefore I must not tell the student that *this* knowledge is less important than *that*, and that one lecture he may attend less diligently than another; I must only speak generally upon so delicate a subject, and contrive to intimate my opinion without giving offence. The prudent householder, when he would furnish himself a house, sees well enough that some things are of mahogany, and some of rosewood, and others of ebony and gold. He sees much for beauty and much for use, and longs perhaps to possess all. But his question is, "Can I afford to possess them?" and his answer, "No, not at present; and I must wait until I can." So, when there is laid before the student this magnificent furniture of the mind, and he asks himself, "Can I possess it?" I will answer the question for him—"No, you cannot at present." "But can I ever possess it?" "Certainly you can." "But how?" "By diligence and by *time*. Your studies will not be limited to the period of your pupillage, and you will know all these things in *time*; but certainly not in the brief space of two years."

Observe, I am not captiously finding fault with those formal requisites of medical education. The things themselves are excellent. But I cannot help wishing, either that fewer had been demanded, or that more time had been allowed for mastering them.

But, after all, perhaps I am wrong. I am judging other men by my own standard; I am taking my own capacity as an average of the generality, and concluding that what I could not do satisfactorily in a certain time, so neither can others. Perhaps this does not follow: I am more than twenty years older than you are; and they say that young men are much cleverer now-a-days than they used to be. I have no doubt they are; therefore pardon my impertinent remarks, and go and learn twice as much as I have fancied you will, and, by a double proficiency, give a noble refutation of my fears—to your own exceeding honour and my exceeding discomfiture.

But when all the lectures in question have had their share of attention, and you have brought away from each what information you can, your most important business, to which all these serve but as the humble instruments, is still to be performed:—you have to learn disease, and how to treat it; and there are lectures immediately subservient to this purpose, viz. lectures on the principles and practice of medicine; also clinical lectures; also attendance at the bedside of the sick; also examination of the bodies of those who die.

Now lectures on the theory and practice of medicine profess to teach physic systematically, and to give an entire view of the subject down to the present day. They are a kind of medical orrery, in which fevers and inflammations, exanthemata and

hæmorrhages, profluvia and cachexies, are made to perform their circumvolutions with wonderful order and propriety. But, as the youthful astronomer needs to contemplate some mimic shew of the heavens, before, with Galileo, he can profitably scan the heavens themselves, "at evening, from the top of Fesolè;" so the youthful physician needs some orderly representation of the whole, to make him know and admire the extent and nobleness of his art, before he begins to deal with its important realities.

Beware, however, of mistaking the intention of these systematic lectures on medicine, or of allowing your minds to rest in them for purposes which they are not intended to serve. They are introductory, and only introductory, to knowledge which is to be acquired by other means. These means are necessary and indispensable—so absolutely indispensable, that, without these means, there can be no knowledge. The knowledge in question is the acquaintance with diseases in all their forms, and the acquaintance with remedies in all their kinds, and all their modes of application; and the means in question are intercourse, continual intercourse, with the human beings who are the subject of diseases. Diseases are not abstractions; they are modes of acting, different from the natural and healthy modes—modes of disorganizing, modes of suffering, and modes of dying; and there must be a living, moving, sentient body, for all this.

This body must be your study, and your continual care—your active, willing, earnest care. Nothing must make you shrink from it. In its weakness and infirmities, in the dishonours of its corruption, you must still value it—still stay by it—to mark its hunger and thirst, its sleeping and waking, its heat and its cold—to hear its complaints, to register its groans.

And is it possible to feel an interest in all this? Ay, indeed is it; a greater, far greater interest, than ever painter or sculptor took in the form and beauties of its health.

Whence comes this interest? At first, perhaps, it seldom comes naturally—a mere sense of duty must engender it; and still for a while a mere sense of duty must keep it alive. Presently, the quick, curious, restless spirit of science enlivens it; and then it becomes an excitement, and then a pleasure, and then the choicest food of the mind.

When the interest of attending the sick has reached this point, there arises from it, or has already arisen, a ready discernment of diseases, and a skill in the use of remedies. And the skill may exalt the interest, and the interest may improve the skill, until, in process of time, experience forms the consummate practitioner.

But does the interest of attending the sick necessarily stop here? The question may seem strange. If it has led to the readiest discernment and the highest skill, and formed the consummate practitioner, why need it go further?

But what if humanity shall warm it? Then this interest—this excitement—this intellectual pleasure, is exalted into a principle, and invested with a moral motive, and passes into the heart. What if it be carried still further? What if religion should animate it? Why, then happy indeed is that man whose mind, whose moral nature, and whose spiritual being, are all harmoniously engaged in the daily business of his life; with whom the same act has become his own happiness, a dispensation of mercy to his fellow-creatures, and a worship of God.

Such a man any of you may be; but you must begin by learning to stand by the sick bed, and make it your delight.

But the interest of attending the sick (I have said) seldom comes naturally; it begins in a sense of duty. All men, especially young men, have a repugnance to scenes of misery. A single object of wretchedness is enough to disturb one at first; but to find one's self at once transported into a throng of objects, where all are wretched, is apt to give a wrench to the spirits from which they do not always easily recover. It is here then, just at the threshold of his practical studies, that the young man must rest upon his sense of duty. His sense of duty must rally him, and support him, and bring him back to the objects which he is so reluctant to face; and the interest will follow, if he is but just to himself.

I have now been a hospital physician many years, and many a succession of students has passed before me. I have not been an inattentive observer of their habits, and have remarked some things respecting the growth of this interest for the practical objects of our profession, which are really very curious.

At first all students are averse from visiting the sick; they have no fancy for the wards either medical or surgical, and they especially shrink from the surgical. But when the repugnance is got over, and an interest begins to be felt, that interest is almost sure to be for surgery in preference to medicine; and yet, when they settle in life, their skill in surgery will be little called for, but nine out of ten of the cases which they treat will be medical.

Now one reason why surgery is more popular than medicine, is, that it is easier. Do not, I beseech you, imagine that I wish

to disparage surgery. In a profession like ours, nothing can shew such bad feeling, or such bad taste, as purposely to let fall expressions which cast an imputation of inferiority upon those who happen to cultivate a different portion of the same field of science and usefulness from ourselves. And even here I will allow, if you please, that cases occur in the department of surgery, beset with difficulties and perplexities, which we in the department of medicine do not meet with, and which require information and judgment and skill of the highest order to surmount.

But I am now speaking of the ordinary routine of cases, such as we find them in hospitals; and, upon a comparison of such cases, surgery is certainly much easier than medicine; and students take to it the more kindly because it is easier.

Surgery, for the most part, requires fewer circumstances to bring you to a knowledge of its object than medicine does. In surgery there are prominent points of interest, which arrest and command the attention at once; in medicine the points of interest are to be sought after, and, being found, are to be retained and cherished by much labour of the understanding. External sores, external inflammation, and broken bones, require only to be seen and handled in order to be known. But the same knowledge which in surgery is obtained by the use of the senses, in medicine, which is conversant with internal disease, can only be acquired by a process of reasoning; and reasoning is more difficult than seeing and touching, and its conclusions are more uncertain, and much more liable to error.

Moreover, the adaptation of curative means requires more vigilance in medicine than in surgery. There is no end of the circumstances to be taken into consideration, day after day, in order to practise medicine with tolerable success. A man has an *external* inflammation: the surgeon sees it, and is at once sure of its existence; he prescribes for it, and sees its gradual decline as plainly as he first saw its rise and progress. A man has an *internal* inflammation; but the physician, not seeing it, is obliged to come to the knowledge of its existence by a great variety of considerations: he prescribes for it, and is again obliged to enter into a variety of considerations before he can know that it has begun to decline or has ceased. The uncertainty of physic I readily admit; but I do not admit the vulgar reproach which has followed from it. There is nothing absolutely sure but what rests upon the basis of numbers, or falls within the sphere of the senses. Where reasoning begins, there begins uncertainty; and on this account the highest and the best things in the world are all uncertain, and so is our glorious profession. But from this very uncertainty those who practise it successfully claim their greatest honour: for where there is no possibility of error, no praise is due to the judgment of what is right.

Another reason why surgery is more popular than medicine, is, that it is easier for pupils to make surgical cases a matter of discussion and conversation among themselves, and thus to convey an interest to each other respecting them. They can agree about the extent of this burn and that fracture, and understand each other when they talk about them; but concerning the progress of a fever, and all its circumstances—how they differ to-day from what they were yesterday, and what influence the means employed have had in determining the changes which have taken place—it is quite impossible that they should have any very general conversation. It is necessary to be in the presence of the patient to point them out. Language often fails of terms to designate them; and the most experienced often find a difficulty in making themselves intelligible to each other in speaking of them. There once flourished within these walls "the Medical and Philosophical Society of St. Bartholomew's Hospital." I fear it exists no longer. The time was that it was attended weekly by at least an hundred students and others. There was often no lack of discussion, and good discussion too, upon professional subjects: but the subject was almost always a *surgical* subject. I have already shewn the reason why it was so—it could not be otherwise.

Again: young men like to be doing something—something that shall be real employment. Thus they are gratified while they are plaistering, and binding, and dressing, &c. They see and they feel that they are promoting some object daily and hourly, with their own hands, for the benefit of the sick. But in medicine, the quiet and almost passive manner in which they are engaged about the sick requires a state of mind which is seldom possessed in early life.

Why do I mention all these things? In order to shew you that I am well aware of all the circumstances which are apt to abate your interest for that department in which it is my duty and my desire to promote your instruction, and of all the difficulties I have to encounter, when I attempt to win you to it.

May I here be permitted to say a few words concerning myself? My office, as one of the physicians to this great hospital, makes it my first professional duty to further the studies of those who resort hither for instruction. A certain depart-

ment is allotted me, and within that department I have, upon deliberation, chosen a certain course. If it be not essentially the best, it is at least that in which I feel myself to have the greatest capacity of usefulness. I desire that you should know what that course has hitherto been, in order that you may understand what it will be henceforward, and what you are to expect from me.

I have been physician here eight years. Having no formal lectures to give, I have considered my business to be expressly in the wards of the hospital; and I have thought myself expressly placed there to be a *demonstrator* of medical facts. I use the term *demonstrator*, because it will at once carry my meaning to your minds; which is, that I have looked upon myself as engaged to direct the student where to look for, and how to detect, the object which he ought to know; and, the object being known, to point out the value of it in itself and in all its relations.

In prosecuting this my duty, I have risen early summer and winter, and have betaken myself to the hospital the first of my brethren; and I have had a purpose in so doing. I have desired to meet the students before their minds were pre-occupied with other things; that, among the interfering demands of other objects which arise in the course of the day, they should not have to catch a moment for that which (I consider) is the greatest of all—to steal a brief interval between lecture and lecture, and give it to that to which all lectures, and all the knowledge conveyed in all lectures, is but subsidiary and subordinate. I would not thank them for such an irksome wearied attention; I want them when their minds are fresh; and therefore I have always given myself to them when mine is fresh.

My visit to the hospital has occupied generally two hours; sometimes a little less, sometimes a great deal more. Half an hour of that time would be sufficient for me to prescribe for my patients, as well as I could, and satisfy my conscience that I had done them justice. The remaining hour and half I have given to the duties of my office as a teacher of clinical medicine.

But in this business of clinical instruction, I have not been the only instructor, nor have the means of information been limited to what I say or I point out. Surely this would be a poor kind of schooling—a giving and taking of scraps of knowledge, where one mind receives just so much as another mind may have to bestow. No; it has been my chief care to put every thing about the sick in the point of view most favourable for being well observed—that circumstances might become didactic—that they might give their own intimations, and speak to you themselves in their own tongues—and that thus you might accept knowledge neither from me nor from any one, but gather it fresh from the reality. Such, I consider, is the true method of clinical instruction. In short, whenever I have entered my wards, I have been accustomed to regard myself in no other light than that of one who presides over a great solemnity, and is engaged so to manage all its circumstances that they should produce their appropriate impression upon the mind of the spectators. You are those spectators; and the solemnity you witness has many scenes and several actors, and one main subject runs through the whole. The scenes are the diversified incidents of many diseases—the actors are the sick themselves, and those who minister to them—the nurse, the physician, and the physician's attendants; and the great subject of the whole is the life of human beings consigned to our hands for a time, and used and treated according to our good pleasure, and always for purposes of good. This life is by all means to be saved; its diseases by all means to be alleviated or cured; and the arts and methods of saving and curing, and alleviating, are to be so displayed that the benefit and blessings of individuals may be multiplied infinitely.

But how multiplied infinitely? Even through you. Recollect you are the spectators; I am but the actor. For this is a case in which the spectator's place is a thousand times more important than that of the prime agent, if the measure of things be calculated by the result. My business is with the few individual patients before me; and whatever good or whatever evil I do, would be strictly limited to them, but for your presence. Yes, you are there to take note of the errors into which I may fall, that you may avoid them, and so restrict the mischief within its present sphere; and you are there to take note also of the good which I may do, and learn the method of doing it, and make it your own, and carry it abroad with you, that it may bear fruit an hundredfold, and be multiplied among all mankind.

You will perceive, then, that with me clinical instruction is, as little as possible, a matter of formal lecture. I will tell you the manner of my proceeding.

Upon the admission of a patient, my first object is to learn the exact nature of the disease I have to deal with; and this is done by my own observation, and by inquiries to which the patient himself or his friends make answer. This is taking the case.

Now, in taking the case, I desire always to proceed after a certain method; and when I am able to pursue that method, all the circumstances which I seek to know

unfold themselves naturally and easily, and then it is a simple, agreeable, and interesting employment.

But often, very often, I am driven from all pretence of method in taking the case. The poor patient is embarrassed by the novelty of his situation, or he is deaf, or his disease incapacitates him; and he hardly understands your questions, and gives you strange answers. Thus things drop out confusedly one after another, and you must be content to accept them as they come, and join them together as you can. But upon these terms, taking a case becomes a very irksome, disagreeable business.

In taking the case, however, if I am able, I always proceed thus:—

The patient being placed before me, I ask him no question until I have learnt every thing worthy of remark which my own eyes can inform me of. His physiognomy—his complexion, whether florid, pale, or dusky—the general bulk of his body, whether large and full, or spare and wasted—the condition of particular regions, whether swelled or attenuated; and of the surface, whether there be any eruptions or sores upon it, and what is their character—and, lastly, the power of locomotion, whether he have free use of his limbs or no.

All these are most important particulars, and we ought to make much of them. There can be no doubt concerning them; they are objects of our own observation, and come to us authenticated by the testimony of our own senses. One step securely ascertained leads to another; and from what we see upon the exterior, we obtain a clue for directing our inquiry to the seat and centre of the disease within. If locomotion be hindered, we look well to the brain and spinal marrow; if there be the livid lip and dusky skin, we scrutinize particularly the condition of the heart and lungs; if the whole body, or some of its parts, be attenuated, we examine well the organs of nutrition.

Having thus learnt all I can with my own eyes, and felt the pulse and seen the tongue, I next proceed, in taking the case, to that further inquiry in which the patient takes a part: and first, I ask him concerning his general sensations, especially whether he is hot or cold, and I endeavour to learn whether his heat and cold occur under conditions which constitute fever.

Next, I inquire into the state of particular organs; and beginning with the head, I ask after pain, vertigo, and a sense of weight—the sight and the hearing, and sleep and wakefulness. Many of these things are only glanced at, or perhaps passed over altogether, if there be no reason to suspect disease of the brain.

Then, passing to the chest and respiratory organs, I ask concerning pain and cough and expectoration, and the state of the breathing under various conditions of exertion and in different postures of the body; and I learn the force and extent of the heart's pulsation.

These things are hardly dwelt upon, or soon dispatched, if there be no suspicion of disease in the chest; but if there be, not all we can learn by simple inquiry is enough to ascertain its nature. The patient must, moreover, be submitted to the process of auscultation. This process, however, in order to avoid interruption, I postpone until other inquiries are finished.

Lastly, proceeding to the abdomen, I ask here also concerning pain and uncomfortable sensations—the appetite—the digestion—the evacuations, their frequency, the quantity and appearance; and then I ascertain with my hand its form and fulness, the possible enlargement of particular viscera, the effusion of fluid, or the existence of pain upon pressure.

Here the examination of the patient ceases, as to his present condition; but the history of his complaint remains to be learnt—its origin and its progress hitherto, and its probable exciting cause.

Perhaps it would seem more in the order of nature, and therefore the best method, to take the history first of all. Formerly I used to do so, but I found it practically inconvenient. If you first learn the existing complaint, you know how much of its previous history you will require to illustrate it; but if you first inquire the history, since you do not yet know what it is to illustrate, you cannot tell how much of it you shall want, and must allow the patient to tell what he thinks fit; and, since every person's complaint is interesting to himself, he is apt to discourse about it rather too much at large, and too little to edification. Therefore it is, that I now always inquire the history last, inverting (if you please) the order of nature; and I take care to make the patient answer express questions rather than leave him to expatiate at his own discretion.

And now the case is taken and recorded in a book by the clinical clerk—not that I deliver over to be recorded all the circumstances that come out in the progress of the examination, but only such a selection of them as may serve to declare the disease, and furnish guidance and direction in the treatment of it.

The case, I say, is now taken, provided there be no suspicion of disease in the chest. But if there be, the patient must be submitted to the proce s of auscultation.

What auscultation is, and the philosophical principles which recommend it as an instrument of diagnosis, it belongs to the lecturer on the principles and practice

of medicine to teach you. But as, in the course of my clinical instruction, I shall lay great stress upon it, and at every visit shall present you with instances of the necessity of using it, and shall invite you to give much time (for much will certainly be required) in order to learn to exercise it skilfully, you have a right to expect from me, who have employed auscultation in this large hospital between seven and eight years, some observations concerning it, and some estimate of its value.

The more accurate physicians of our own times have not disdained the guidance of another sense in the investigation of disease. They make use of the hearing as well as the touch and the sight, and in those things which are more fitly and naturally subjected to it, they have found it not an unfaithful interpreter of the truth.

Auscultation, as it is called, professes to furnish important aid in the diagnosis of diseases appertaining to all the organs within the chest. Its use, however, has not yet become popular in this country, nor is its value ascertained.

There are those who condemn it as absolutely worthless, and there are those who commend it as infallible.

Its vehement and unqualified condemners, judging from what they write and say, are absolutely ignorant of, and unpractised in, its use; and its unqualified commenders are probably of that happy temperament which is naturally averse from admitting the real difficulties of any subject, and therefore find none in medical diagnosis, which is of all things the most difficult, whatever be the means employed for its illustration.

But there are many sober, well-informed men, who, having the opportunity, have thought it their duty not to spare the necessary pains of practically acquainting themselves with a method of inquiry which comes recommended to the world by one of the soundest pathologists that ever lived: and among these there will not be found one who does not attach some (and that a very considerable) value to its use.

A priori it would not have been believed that the pulse could ever teach us what it does. Sir John Hawkins, when he visited Dr. Johnson one day during his last illness, says, "before my departure, Dr. Brocklesby came in; and, taking him by the wrist, Johnson gave him a look of great contempt, and ridiculed the judging of his disorder by the pulse."

If we had heard, for the first time in our own day, of some physician going about this town and putting his fore-finger upon the wrists of his patients, and professing to know, from something he found there, that this man had an inflammation of his lungs, and that man of his bowels, and presuming to prescribe bleeding and other gigantic remedies, simply from faith in his own infallible fore-finger, grave men would denounce him as a dangerous quack, and pleasant men would hold him up as a fair subject for ridicule.

Yet use has so educated the fore-finger of us all, that this is the very thing we are now doing every day of our lives. When, therefore, so much is confessedly learnt by one sense, it is rather hasty to conclude that nothing whatever can be learnt by another. When, by touching an artery, be the disease what it may, and seated in whatever part, we seldom fail to gain some knowledge concerning it, and some suggestion how to treat it, why should it appear incredible that two particular organs only—the lungs and the heart—should submit some of their diseases to the cognizance of the ear?

Concerning the sense of hearing, in relation to its proper objects, and in relation especially to diseases of the heart and lungs, no man can learn from another the kind of information which it is able to convey; every one must teach himself. In this respect it is with hearing as it is with touch. You may talk of a hard and a soft pulse, of a full and a small, of a quick and an irritable pulse; but be assured you thus convey no intelligible idea, except to those who are by practice as conversant with the pulse as yourself. So, too, with respect to the heart; you may talk of its sound being clear or dull, near or distant, limited or diffused; and, with respect to the lungs, you may talk of the bronchial and vesicular respiration, of the bronchial voice, and pectoriloquy, of rhonchus and sibilus, and large and small crepitation; yet none can understand you but those who have given much time and pains to the exercise of auscultation.

Let us recollect that the pulse submits none of its qualities, but those which respect its number, to actual measurement; all the rest are determined according to the perceptions of the person who feels it. Yet, concerning these, there is a tolerable agreement among medical men. It is the same with the heart. The number of its contractions may be counted, and therefore never can be doubtful; but the modes and qualities of its contractions, which are many, are determined according to the perceptions of the person who hears them. These, however, like the kindred qualities of the pulse, are accustomed to strike all who habitually attend to them in the same way.

Summarily, then, concerning auscultation, my experience (I think) warrants me in saying thus much:—1. That there are some diseases of the chest which in their *kind* entirely elude it; 2. that there

are some which elude it not in their kind but in their *situation*;—3. that there are some in which auscultation is only a help to diagnosis, but still a very great help;—4. that there are some (and perhaps the larger number) in which the conclusions of auscultation are as unerring as those of sight itself.

Certainty is a big and portentous word, applied to any the smallest portion of our art. But still there is a small district of the whole field of diagnosis, but a large district as it respects particular organs, which auscultation has rendered absolutely certain.

With auscultation I almost always use percussion, and the results of the one perpetually correct or confirm the results of the other, and strengthen the diagnosis.

But does all clinical instruction consist in directing the mind how to ascertain mere particulars, whether by auscultation or percussion, or by whatever other method is adopted for their discovery in different organs? No. Clinical instruction is not merely occupied in directing observation to facts, but it assists the mind in estimating their value. Thus when the record of the case which is taken has been read aloud, I admit you to share in all the little process of deliberation that is going on in my mind, as it works upon the materials just submitted to it, and I admit you to witness my endeavour to bring the particulars together, and make them contribute all the light they are capable of throwing upon the nature and seat of the disease. Sometimes I can at once come to a confident diagnosis, and when I can, I at once announce what it is, and give my reasons for it.

Sometimes, after great pains of inquiry, I am still in the dark, and when I am, I say so, and desire to reserve the case for future examination.

Sometimes, perhaps most frequently, I feel that I have a tolerably right notion of the complaint, but require some circumstances to be more clearly made out, before I can be absolutely certain. And then I state what are the circumstances which give me the notion that I have, and what I still desiderate to bring me to a more confident conclusion.

The case still remains to be prescribed for. In prescribing, I endeavour to be as simple as possible—to make the indications of treatment as intelligible as possible—and the object I have in view clearly seen.

The case thus examined, and commented upon, and prescribed for, I then commit to your future observation as a medical study.

In the further progress of the case I am still present, not to give formal lectures, but to take care that none of the circumstances which continue to develop themselves may fall to the ground profitless; and that you may be tutored by *them*, and not by *me*.

Not one only, but many cases, I shall thus consign to your study with the like care; and in all I shall be continually at hand to render you my assistance. That assistance, however, I shall never interpose, so as to hinder the exercise of your own independent observation, and mar the very purpose of clinical instruction.

With respect, however, to formal lectures, as a part of clinical instruction, I will say this: that the teacher would do well occasionally to call his pupils together, and state to them his own views (for every man *has* his own views) of certain leading points of pathology; for these views, he must be conscious, give a bent and direction to every remark he makes upon the objects which he and his pupils are daily contemplating together; and it is desirable that they should have the best key to interpret him by, since they ought to understand each other. This would require a formal lecture.

Again, for the same reasons he would do well to acquaint his pupils with any general principles at which he may have arrived in the treatment of disease. This, too, would require a formal lecture; and such lectures I am almost tempted to promise you, if I was sure they would be acceptable. But it must not be yet; for I am not certain that we should at present quite understand each other upon these interesting subjects.

The progress of the human mind is evermore from particulars to generals; and he that would inform others must be careful, in the manner of his teaching, not to transgress the order of nature. Full of this important truth, I must first seek to rivet you to the contemplation of individuals, and only venture to unfold to you any general principles, which I may conceive myself to have reached, either of pathology or practice, in proportion as I judge you able to authenticate them by your own growing experience.

But it is *your* present duty to exercise your observation carefully and unremittingly; and it is *my* present duty to point out the fittest objects, and place them in the light in which they can be most profitably seen.

If ever the desire to view the beauties and sublimities of nature has led your footsteps to some lofty eminence, you have probably taken with you one more familiar with the scene than yourselves, as a guide; but you have still trusted to your own eyes and your own feelings, to fill you with the delight of the prospect, and tell

you what to admire and wonder at; and you have required no more from the guide than to point with his finger, and say, "see here, and see there."

So in entering this place—even this vast hospital—where there is many a significant, many a wonderful thing—you shall take me along with you, and I will be your guide. But it is by your own eyes, and your own minds, and (may I add) by your own hearts, that you must observe, and learn, and profit: I can only point to the objects, and have little more to say, than "see here, and see there."

ON THE ANALOGY

BETWEEN

THE GRIPES IN HORSES AND THE EPIDEMIC CHOLERA.

By Eracy Clark, F.L.S.
Member of the Royal Institute of France.

In the midst of the numerous, opposite, and very conflicting opinions, which prevail at this time respecting the direful epidemic called cholera, and which still exerts its fatal ravages in spite of all that has been done, and which opinions respecting its nature and its treatment seem almost as various and unsettled as they were at the first commencement of it, if we may judge, at least, from the recommendations every day proposed in the medical periodicals.

Under these circumstances you will, perhaps, pardon the suggestions of one who, though formerly educated for it, is not now strictly one of your honourable profession, and permit him to advance an opinion which he has long entertained, and which, if it be not founded on truth, has one merit at least—that of novelty. These opinions have, however, been shewn to a few of his medical acquaintance, who do not see any thing in them to forbid the reasonings and conclusions here drawn; which has induced him—with great deference, however—to make them more publicly known. If they should be at all admitted, they will certainly lead to a more decisive, and perhaps more successful mode of treating this disease.

Many physicians have, I believe, been of opinion that this epidemic, though designated cholera morbus, was not properly that disease, at least according to the definitions given of it by the best nosologists: but what it was, they have left undetermined, or by what name in their system it should be called. Indeed, that it could not very well be cholera morbus, being for the most part deficient in the grand character of that complaint, as its name, indeed, implies, of purgings with increased biliary secretions; for this secretion seems often morbidly suppressed and almost entirely wanting in well marked cases of this disorder; and the diarrhœa which sometimes precedes it we believe to be no part of the disorder, but as sometimes leading to it, by its weakening influence upon the general system, and especially upon the parts immediately concerned; but in very many cases it is not present at all, and therefore is no necessary concomitant or character of the disease.

Perusing the various descriptions of this disorder, I have been a long time firmly persuaded that its prevailing character bore a nearer analogy to a complaint that I had had often to contend with among animals, than to any enumerated in the books on human nosology; and that, in fact, it was a more or less complete suppression of the process of digestion or chylification, as we shall presently illustrate by actual cases, and that it bore a nearer analogy to, and was proceeding very much from, the same fatal causes as the stroppos, or the gripes, in horses; in which, in the early part of my practice in this great metropolis, I had had a large and not unsuccessful experience, having discovered its true cause and a successful mode of combating it.

Attacks of this complaint, like the cholera, often carried off the animal in a few hours; and in the commencement of my practice, though employing and using all the then known and recommended remedies (and such are sure to be numerous and discordant enough, where the character of the disease and its treatment are not understood), I frequently lost my patients. Fearful of losing my credit also, I took unusual pains, by watching, dissection, and otherwise, in satisfying myself of the nature of the disease, and of what should be its proper treatment, and at length so far succeeded that for years I never lost a patient, often contending with protracted and cruel cases. The success that attended

my treatment induced me, for a considerable period, to keep it a secret, and it was extensively sold privately; but, at length, becoming more generally known, and abused also, and not given with the laws prescribed with it, I determined on publishing an account of it, and (what was of fully as much or more consequence) my views respecting the nature and causes of the complaint, and how it should be treated by properly sustained measures in aid of the medicine.—(See "Essay on Gripes of Horses," London, 1816.)—I believe, in the different large breweries in this metropolis that I at that time attended, some thousand pounds worth of horses were saved by what I called a duly sustained treatment of the complaint, of which testimonies were given me, which appear at the end of the above treatise.

In respect to the cause of the disease, I traced it satisfactorily, at its commencement, to an insufficient power in the alimentary organs to carry on and perfect the digestive process, either from the accession of some debilitating cause, which rendered these organs unequal to the task, or from the unfavourable nature of the contents of the viscera as to quality or quantity, or from both or all these causes combined. The lowering agency of a sudden chill to the abdomen would alone produce it under ordinary circumstances, and still more easily if a refractory quality or unusual quantity was superadded. Derangement or suppression of the chylifacient process would take place in the intestines, and the disease be carried on there to its termination in death; or it might be communicated by sympathy or by connexion to the stomach, or *vice versâ*, beginning in the stomach and carried to the bowels. In either case, the suppression or arrestation of the digestive process would quickly produce *tormina*; which, if not relieved by the restoration of digestion, would quickly terminate in death, either by inflaming the mucous membrane of the bowels or stomach, or by its operation upon the brain through the agency of the nerves of the stomach. In horses, who could withstand a severer shock of this sort than the more sensitive human being, inflammation would have time to establish itself pretty fully in the membranes of the bowels, and produce appearances not very unlike what Dr. Annesley has given in his work on Indian Cholera; for extreme violence in the attack from several causes, combined with great strength of constitution to resist it, would have much the same effect in the animal as often happened in the cases related in India.

We may, perhaps, illustrate the cause of the sudden termination of the complaint in the following way:—that many substances assume a poisonous quality if they are not digested, but if digested they are perfectly inert.

If you give to a horse four ounces of the leaves of the yew tree, on an empty stomach, it will destroy him in a few hours, and but a very slight appearance of inflammation will the stomach exhibit, in petechiæ or spots of the size of the little-finger nail. But if to this quantity of the acrid vegetable you add eight ounces of oats, and mix them together, he will eat the whole, will digest them well, and will not even be incommoded: so that, in the former case, it must have been destroyed by the influence of the undigested matter upon the brain, acting on the nerves of the stomach before the other symptoms attending the suppressed act could have had time to display themselves.

It may be asked what should be the cause of this epidemic at this particular time, and why it should be almost wholly, if not quite, a human one? This I would not undertake to account for, any more than the plagues in Egypt or Jerusalem, or the causes of any other scourges with which the Almighty at times has assuredly visited mankind. I can, however, in reply to it, only just observe, that if the atmosphere was, by any changes in it, rendered less stimulant to the ordinary act of human digestion, it would readily produce such an effect; nor could we, perhaps, by any analysis detect it, though it is possible that we might, if truly, anxiously, and industriously employed upon it. That the atmosphere, for a long time past, has been more thick, turbid, and hazy, than I ever remember it before, I can from frequent observation testify; but whether this appearance did or did not belong to the production of the disease, I do not undertake to determine, though I fully believe so: admitting, however, but for a moment the position, we should then see that the weak, the debilitated, the intemperate, the drunkard,

the imprudent, and the exposed, would be the especial objects of its visitation; as, in fact, they have been amongst its most frequent victims. General Diebitz was a remarkable instance of it, being a wholesale devourer of punch.

No better account has ever yet been given of the immediate cause of many a pestilence, many a fever and plague, and for which we can only present as a cause the inapplicable general term malaria, or the Almighty will, and no further yet have the profoundest researchers into primary causes been able to get.

One of the best related cases I have seen of the cholera, and most minutely detailed, was that of a gentleman at or near Glasgow, I think, who had eaten an unually hearty meal of pickled salmon, being fond of it. The mass was too considerable, either from the quantity itself or the debilitating influences of the malaria, or both, for it to pass through the usual stages of chylification; he was seized with what were called the genuine symptoms of cholera, which no one ever disputed they were, and he died. Now all the circumstances here could be readily explained upon those principles which I have laid down in explaining the gripes of horses; but there, in some of the most violent and rapid cases in their termination, we had a direct and visible cause in a chilling atmosphere, with or without rain, and the animal also sweating from labour at the time of its application, and thus doubling the chill. The magnitude of the intestines of the horse, —the prodigious mass they would contain of vegetable food, least liable of any to digestion—the thin membranes composing them, rendered them quite unequal to the task of carrying on the digestive process under such untoward circumstances; and digestion ceasing, and the disorder once begun, lead to others producing active inflammation in the mucous membrane, brain affections, &c.

Now what have been said most to produce this cholera was the eating of cucumbers and melons, and unripe fruits, and hard meats;—and why? because these are amongst the most difficult of the vegetable tribes of digestion, and, refusing digestion, they become poisonous, and so do they act in producing *tormina*, wreathing and knotting of the abdomen; and from whence the ancients called it *strophos*—from the verb *strepho*, to turn, twist, or writhe about. And may we not also readily account for the extraordinary coldness of the tongue, so often noticed, on these principles—from the chilled and rigid state of the stomach and the total absence of digestive power, the blood then retiring to other parts of the body?

In respect to the cure, which all will be desirous to know, it consists only in well-known remedies; but their operation is rendered more effectual by understanding the nature of the disease and the point to be obtained—viz. *the restoration of the digestive functions at all events*; for before I found this, I rested when the remedy had been given, nor knew what to do if it did not succeed or take effect, the practice being almost purely empirical; but if the train of operations in the stomach and bowels were not restored at one dose, I aided it by a repetition, regardless of the terrors about inflammation, a bugbear which former idle apprehensions had filled me with, by other measures also nearly as potent, and pursued it without delay with a second, a third, or a fourth or fifth, till I saw the healthy actions return, or a recommencement of the digestive process; which being sustained by prudent measures, the case did well. If inflammation had begun, some slight after-treatment might be necessary.

With the horses, I led them to a warm place, shut all the doors and windows, covered them with rugs, threw down straw for them to roll upon, and gave them successive doses of the tincture of pimento—about a quarter of a pint at a dose, waiting half or three-quarters of an hour between every dose. Getting my hands under the rugs, I rubbed the abdomen with flannel; and sometimes, with all this it took seven hours, in very bad cases, to restore the digestive process, but many a one supposed to be dead recovered; for the relief is so great and soothing to them after the excruciating agony they had suffered, that they doze often on losing their pain.

I will now relate a human case, and its treatment. A very respectable middle-aged woman, in service, not far from my house, had eaten a free, but not very copious, dinner of liver and bacon, and, I believe, had taken porter instead of water with it. She dressed and went out in the afternoon, with a friend, to

the Bazaar in St. James's-Street, and loitering about to look at the various articles, and a wind blowing through the avenues of the place at the time, she suddenly became uneasy, and soon in violent pain. She returned home as fast as she could, and complained very much of sickness and a deep, oppressed, painful feeling about the præcordia. She vomited violently, but this did not relieve her pain, which became excruciating. I then ordered her to shut the door of the apartment she was in, and to put the kettle on, with a pint of water—this small quantity only, that it might the sooner be heated; and of this, when nearly boiling, I made her drink, as hot as she could in any way get it down, three parts of a pint; her vomiting continued, however, and her pain. I next, therefore, ordered half a pint of hot ginger-tea, which she also took, but without relief. About an hour had passed over in this way, still in severe pain. I now ordered her to bed, sending with her a good pan of hot coals to warm it well first; and to this I added a glass of hot gin and water, a little sweetened, which she sipped as hot as she could take it. In less than five minutes after she felt a sudden remission of the pain; she slept well after, and the next morning was at her work as usual. She seemed, however, headachy towards the afternoon, and I recommended a dose of Glauber and Epsom salts mixed, which restored her usual health.

A few days ago, a gentleman of my acquaintance, whose son was not unacquainted with my opinions respecting this complaint, was suddenly seized one evening with excruciating pains about the præcordia, and unlike any thing, in point of severity, he had ever experienced before: he compared it to being screwed through with a screw. A fire was made in his room, and brandy and water pretty strong, with laudanum, (which I do not recommend,) was given him by his son; and, at the end of two hours, by these remedies, and with rubbing the abdomen with flannel, he was relieved, and was out the next day on his morning walk, when I saw him and heard his description of what he had gone through; and his son related to me what he had done for him. I consider myself as having been twice attacked with an arrested digestive process, and which, if permitted only a short time to have gone on, would have ended in what is called a true cholera (for names, though simple, are frightful things often in misleading our views.) I immediately closed the apartment, took to drinking hot water (as hot as I could in any way get it down); I sat by the fire and rubbed, with a flannel bag over the hand, the abdomen, and in a quarter of an hour had dispelled the symptoms. This is the simplest form, perhaps, of the complaint, or rather the point of commencement of it, when it can be more easily subdued—especially if there be no great opposition from the mass of food or its quality being very refractory, and the animal powers in tolerable force. The knotted state of the abdomen appears to arise from the recti and other abdominal muscles being contracted in sympathy with the suffering parts beneath. For some remarkable cases, where the restoration in the horse was opposed by a combination of untoward circumstances, I must refer the reader to the treatise above described; and for a great deal of reasoning and observation which would be out of place in this small sketch.

As to anodynes or opiates, it must be obvious, relieving pain by mere soothing and lulling the nerves must be nugatory while the cause of that pain remains uncontrolled: I, therefore, early quitted the use of them, and found, by doing without them, their total uselessness; and as bleeding may exhaust the very powers we want to rouse, that I never resorted to till the next day, if any inflammatory symptoms appeared to remain from the lateness of the remedy or the extensive application of it, when a gentle purgative or a venesection was decisive.

There may be cases, though I believe but rarely, when the cardiac system may be oppressed by an overcharge of blood, as in some plethoric people, where *breathing a vein* would set the springs more at liberty for motion, and be of service; otherwise blood-letting I believe not to be necessary, unless to suppress, as we have stated, any inflammation consequent upon the remedy, as that may have arisen from its late application.

After this manner may be successfully treated, we believe, a very great number of these strophic attacks, if for once we may be allowed to drop the erroneous term cholera, for there is cer-

tainly no χολη or bile to characterize the complaint, or concerned in it; but rather, perhaps, a want or suppression of this secretion; and which want of the daily purgative of life adds to the facility of access and severity, perhaps, of the complaint: and may not the diarrhœa complained of in many cases which precedes the complaint, derive its origin from the want of the stimulation of this natural fluid; the intestines inflaming for the want of its usual operation upon them—thus inducing a capillary flow into them and purging—for the same causes that suppress the digestion act, will also diminish biliary secretion.

Though by no means generally, yet in several instances we have seen of late that the remedies proposed were of the description here pointed out Horseradish tea has been given in Lincolnshire, and a cholera tincture is now sold in the shops; but, in the manner of using them, there does not seem to be a full understanding of the true nature of the disease, which they continue to call cholera; nor do they appear to be aware of the necessity of making their treatment efficient by a combined plan of operations in the attacking it: so that their treatment is almost an empirical one, and would not, in this case, be attended with so extensive a success.

If this small communication is deemed worthy your notice, it is at your service, to apply it to whatever purpose you please.

Regent's Park, Oct. 12th, 1832.

ANALYSES OF SEVENTEEN REPORTS ON CHOLERA.

Transmitted to us by the Central Board of Health.

Dr. Maclure, of Harley-Street (Oct. 15.) This, the recent epidemic, not new to this country; had more severe cases of the same kind in the summer and autumn of 1831; has had no patient in the stage of collapse.

Mr. French, St. James's Cholera Hospital (Sept. 18.) From March 25 to above date, admitted 50; dead 21—recovered 22—remaining 5.

1. Bilious diarrhœa. This form of disease I have treated—

a, With mercurial alteratives and mild aperients.

b, With neutral salts (sulphate of magnesia and nitrate of potass), in doses calculated to excite the action of the kidneys and skin, combined with small doses of the tincture of opium.

c, With astringents.

According to the circumstances of the cases.

2. Diarrhœa, with rice-water evacuations. In this form of complaint I have given—

a, Emetics, when the evacuations shewed no decided tendency to amelioration in quantity and frequency.

b, Cold water, supplied *ad libitum*, to quench the patient's thirst.

3. In the stage of collapse.

a, My object has been to endeavour to replenish the system with fluids, by assiduously quenching the patient's thirst with cold water.

b, I have carefully watched the patient, and employed local stimulants externally in case of sudden syncope.

c, I have encouraged nausea and vomiting, as conducive to re-action.

The cases were for the most part of great severity. All those who recovered took cold water *ad libitum*, to quench the thirst; nor were stimulants of any kind taken internally in these cases, till re-action was fully established. Children generally recovered without any consecutive mischief; robust adults generally require bleeding—in some instances several times, and to considerable extent; this, of course, during re-action.

In all cases where ischuria continued beyond the third day, there appeared some disposition to coma; this state was invariably relieved by bleeding—the blood not always, under these circumstances, exhibiting the buffy coat. In general, however, the blood exhibited decided marks of inflammatory character; even on the day following the attack this was sometimes more or less the case.

Dr. Hingston, of Plymouth (Sept. 13.) In the first stage, has seen "numberless" instances cured by a draught containing magnesia, a few drops of laudanum, and half a drachm of compound spirits of ammonia, repeated two or three times, and followed by a full dose (gr. x. to ℈j.) of calomel. In the second stage has great confidence in

mercurials (calomel gr. ij. with opium gr. $\frac{1}{6}$th, or $\frac{1}{8}$th, and mercurial frictions); sinapisms, small quantities of fluid, avoiding stimulants, which have proved "exceedingly prejudicial." In children has seen starch injections, with opium, of use. In the collapse stage has confidence in nothing; where recoveries have occurred, they seem to depend on the *vis medicatrix naturæ*.

Mr. Foote, of St. Hilier's, Jersey (Oct. 15.) Approves of stimulants, and condemns the free use of cold water; speaks in general terms, but adduces no cases nor numbers.

Mr. Baillie, of Poplar, Middlesex, (Oct. 15). In stage of diarrhœa has used, and with success, calomel, followed by chalk mixture, with catechu. In the second stage always fluids freely, and gives four grains of calomel every half hour, for five or six hours, with saline effervescing powders in cold water. None so treated have had collapse. In the stage of collapse, "my first care has been to procure warmth on the surface of the body, and particularly in the extremities, as soon as possible, by means of blankets, bottles of hot water, or the heated air-bath; and next to apply a large sinapism over the abdomen, and one to each calf of the leg; use frictions to the parts affected with cramp, which is generally relieved by the warmth, and give calomel in large doses, with three or four grains of the extract of henbane, every half hour, for three or four hours. Continue the saline effervescing powders, to alleviate retching, and give cold water as often as the patient desires it. Watch incessantly for the least re-action, which in most cases does take place sooner or later (although frequently of short duration), and bleed. At first, with great trouble, I have succeeded in getting three or four ounces only, but have generally had the satisfaction to find the pulse improve, and, in an hour or two after, I have again used the lancet with somewhat better success, when, if the vomiting has ceased, I give two grains of calomel, with one-fourth of a grain of tartar emetic, every two hours, till the mouth is affected and the secretions restored. In this way the last case I had under my care, which was considered hopeless by myself and the other medical men who had seen it, was treated, and perfectly recovered, after having been almost pulseless and in a state of collapse, without passing any urine for 125 hours, during which period he was bled at least once in every 24 hours, and lost, either by the lancet or by leeches applied to the temples, upwards of forty ounces of blood." Has for sometime abandoned the use of opium and stimulants; recommended bleeding and cold water in the fifth number of Cholera Gazette, March 1st. Has had thirty-seven cases in the second and third stages, of whom twenty-two have recovered. Several of the most severe cases, on recovering from collapse, had melœna and hæmorrhage from the bowels.

Mr. Eldridge, of Southwark Bridge Road, treats the disease, in all its stages, with stimulants, opium, and mercurials, in various proportions; external stimuli. Gives no cases or numbers. Has sometimes thought the free use of opium injurious.

Mr. Trotter, of Stockton-on-Tees (Sept. 18th), says, "I was led to the use of frequently-repeated small doses of irritating purgatives, as the most likely means of restraining the discharges. With this intention I have given a combination (in the form of pill) of croton oil (Short's) with calomel and extract of hyoscyamus—one-eighth of a drop of the former, and a grain and a half of each of the latter; and have invariably found it restrain the evacuations. I repeat the pill every hour, until that effect is produced; generally from six to a dozen pills will be required, when the evacuations (if any) will be of feculent matter, or frequently like chopped spinage. I have not found the vegetable astringents of the least use in restraining diarrhœa when it is of the rice-water-like fluid, and have seen it continue for days under their use, when half a dozen of the above pills put a stop to it. At first I gave the croton oil in quarter of drop doses, every two hours; but so frequently found it produce much pain and uneasiness in the stomach, with frequent vomiting, that I reduced the quantity, and found it answer much better. The incessant vomiting was a very troublesome symptom, until I began the use of the Prussic acid, in doses of one and a half to two minims, every two or three

hours, until it abates; which I have invariably found to be the case after three or four doses. I had tried nitrous acid, and various other medicines, with blisters, &c. &c. without the least effect."

Dr. Gillespie, of Lisson Grove, North, also speaks in favour of croton oil:—"I beg to corroborate what has been stated by Mr. Ward, of Wolverhampton, as to the efficacy of croton oil in the treatment of malignant cholera. Since the 9th of last month, when I used it first, I have given it in a number of cases, and of all, some of them the most malignant, have but lost one, an old man of 68. I have also seen its beneficial effects in the practice of Mr. Cunningham, Hereford-Street, to whom I recommended its use, and have received favourable notices of it from two other medical men to whom I had spoken of it. The dark-green evacuations spoken of by Mr. Ward, are very characteristic of the effect of croton oil, and afford hope of favourable issue. When taken, it produces a glow in the stomach and fauces; it certainly acts powerfully on the mucous surfaces, and perhaps on the nervous system; its action sometimes has appeared as sudden as the disease attacks; it has in a few cases removed the pain from the stomach, and arrested the cramps, within ten minutes."

Mr. Judson, of Ware (Sept. 26.) In first stage, a full dose of calomel, succeeded by a mild purgative, and this followed up, if necessary, with absorbents and laudanum. In second stage, calomel and opium, with effervescing draughts; copious clysters of broth, with opium and salt. In third stage, heat, enemata as above, venous injections, &c. &c.; has nothing to say in their favour.

Drs. Miller and Venables (Wick, Oct. 11), from 7th August to 16th October, at Wick, treated 317 cases, of which died 59. This is independent to bilious diarrhœa, of which there occurred 879 cases. Deducting those very far advanced in life, calculates the rate of mortality at about 1:6. In hospital treated 95; deaths 28. With deductions similar to above, rate about $1:4\frac{7}{20}$. Remedies: Salt emetic, warm pediluvium, calomel, Dover's powder, warm drinks. Crisis was evinced by free diaphoresis and bilious evacuations.

Mr. French, City Road. In bilious diarrhœa—calomel and Dover's powder, chalk mixture and rhubarb, &c. &c. In rice-water evacuations—calomel, followed by a mixture containing magnesia, rhubarb, carb. of ammonia, antimonial wine, and tincture of hyoscyamus. In collapse, calomel gr. j., and opium gr. $\frac{1}{3}$, every half hour, with the preceding mixture. No results stated.

Mr. R. Y. Ackerley, Liverpool (Sept. 20), states his practice to have been "eminently successful," but gives no numerical returns. In bilious diarrhœa—a table spoonful of castor oil, with ten or fifteen drops of laudanum, is succeeded by chalk mixture, with tincture of catechu and opium. If bilious vomiting present—saline effervescing mixture. In rice-water evacuations, with incessant vomiting and cramps—first object to check vomiting, and this best done by the powders of Dr. Stevens, containing oxymuriate of potass; has seldom found it necessary to give more than two of these. The vomiting having ceased, gives two table spoonfuls every quarter of an hour, of a mixture containing tincture of opium, spirit. ammoniæ comp., syrup of ginger and water; to which is added, a little tincture of catechu, if purging be present. Two grains of calomel, with gr. $\frac{1}{2}$ of opium, and a few grains of capsicum, every hour till the mouth be affected. In collapse—same remedies, rubbing the abdomen till the cuticle be raised with equal parts of turpentine and liq. ammoniæ, with a little laudanum; warm bags of sand to various parts.

Mr. W. S. Cumming, Limehouse (Sept. 18), treats bilious diarrhœa successfully with common means; calls nothing cholera where there are not rice-water evacuations; in this, prefers twelve grains of calomel at once, with five of ginger; a blister to epigastrium; warmth to extremities; two table spoonfuls every hour of a mixture containing carbonate of soda, muriate of do., and oxymuriate of potass, with a little laudanum and aromatic confection in peppermint water. In collapse—has nothing particular to recommend; thinks we are still "at our wit's end as respects the treatment."

Mr. Wm. Broackes, Regent Place, City Road, Surgeon to the parish of St.

Luke's. In bilious diarrhœa, the ordinary means, such as calomel and chalk mixture, always successful. In second stage, has generally seen the case run on to collapse; uses blankets immersed in hot salt and water wrapt round the body, and a drachm every ten minutes, or quarter of an hour, of the following mixture:—

℞ Træ. Capsici ℥ss.; Opii ℥j.; Spir. Ammoniæ Tart. ℥iij. M.

"Few patients have died since this treatment has been employed." Has abandoned the saline treatment, after having given it a fair trial.

Dr. Lucas, Exeter (Sept. 18.) In bilious diarrhœa—mist. cretæ, with spirit. ammoniæ c., and træ. opii, with a mild mercurial, if stools were dark and fœtid. In rice-water evacuations—a salt, or mustard and salt, emetic; afterwards a table spoonful of castor oil, with a tea spoonful of tincture of rhubarb. If cramp, &c. &c., mustard cataplasms and external heat, and where pulse permitted, V.S. ad ℥x. vel ℥xx.; if face flushed, leeches to temples; calomel, grs. x. to xx. every hour till mouth became sore; if much pain or spasm, a grain of opium with first dose. If vomiting continued obstinate, found "the greatest benefit" from a starch clyster, with a drachm of laudanum; soda water, with or without a tea spoonful of brandy; two parts lime water to one of milk—by spoonfuls at a time. In collapse—spirit. ammoniæ comp. every ten minutes, in hot water; mustard cataplasms, &c. If re-action was procured, large doses of calomel, *small* bleeding, &c.

Mr. Wade, Surgeon, Milbank Penitentiary, (Oct. 11.)—In bilious diarrhœa, calomel and rhubarb in small quantities every two hours, till six doses have been taken; then followed by pulv. cretæ comp. and aromat. confect. in cinnamon water. Allows beef-tea, &c. and sometimes half a glass of hot brandy and water. In rice-water evacuations, three grains of calomel and half a grain of opium every two hours, till six doses: starch enemata, with kino and laudanum. If stomach irritable, effervescing draughts, with a little brandy. Calomel continued, without opium. 235 cases of "cholera diarrhœa" between March 6th and Oct. 11: all cured as above. In third stage, "stimulants are our sheet-anchor;" but adds, "those who recover from a collapse, do so full as soon in the hands of the judicious nurse, and with less dangerous sequelæ, without the doctor." Of 51 cases of collapse, 33 recovered: all different methods tried in these, and the writer "will not say that they were any thing beholden to medical aid."

The report which follows was accompanied by a request that it might be sent to the Medical Gazette: it was sent, however, (of course by mistake,) to the Lancet, and has, in consequence, reached us so late that we have only space left to give the analysis which follows. We think the gentlemen whose practice is described, will feel satisfied that we have omitted nothing essential.

Dr. Symonds, of Bristol.—Report of disease at Cholera Hospital, under the immediate care of Mr. Golney, and daily visited by Dr. Symonds, Dr. Carruck, and Dr. Kentish. Cases admitted have been of the severest kind: little experience within the hospital of "bilious diarrhœa." Such cases as did occur, easily controlled by opiates and astringents, conjoined in one or two instances with a moderate bleeding.

The above treatment utterly inefficient when evacuations had lost bilious character. The bold exhibition of calomel is the measure on which the chief reliance is to be placed,—other remedies being scarcely more than subsidiary. Patient placed in a warm bed; ℥ss. of calomel exhibited in powder; a mustard cataplasm to the epigastrium, by which the vomiting is mitigated; calomel repeated every two or three hours;—where treatment is begun before collapse, rarely more than three or four doses required. As soon as temperature of surface rises steadily and circulation increases, the medicine is suspended. In a few hours, bile appears in dejections, and afterwards is discharged in profusion: urine returns, but always subsequently to the bile. Accessory means not neglected; extremities assiduously rubbed: if vomiting urgent, effervescing draughts; if extremely obstinate, one or two drops of hydrocyanic acid, in aromatic water, has an "excellent effect." Occasionally, when sufferings are great, 40 or 50 drops of laudanum are given. If much thirst, abundance of cold water, except immediately after the calomel. In collapse, same general treatment

pushed to a greater extent; the 3ss. doses of calomel often given to the amount of five or six, at intervals of two hours; occasionally enemata, containing brandy and spirit of turpentine—but some doubt is entertained of these being very useful. "A great number" have been restored from collapse; some from "the most appalling and hopeless degree of this condition."

Preferred the exhibition of calomel in large doses at intervals, as above, both as avoiding unnecessarily often disturbing the patient, and as producing a soothing effect: first dose has often acted "like a charm." Ptyalism too essential to salutary action; many cases of recovery without any sensible effect on the gums or salivary glands.

Various experimental trials have been made of other means—none have been attended with satisfactory results. Neither salines nor cold water capable of overcoming the blue and collapsed stage of the disease. Emetics scarcely attended with better results. The solution of tartarized antimony does not appear to increase the previously existing nausea. Stimulants generally inefficient or injurious. Artificial heat has much less influence than might have been supposed. Opium avoided, except as a palliative for spasm, from a conviction that it is often highly mischievous. Venesection has led to disappointment. Venous injection not tried—experience being now against it.

Consecutive fever treated on general principles; the difficulty being to push depletion far enough for the reduction of local inflammation, but not too far for the strength of the system. Those which have shewn disease of mucous membrane of the bowels, and insidious bronchitis, most fatal; three were convalescent, up, dressed, conversing "jocularly," when all at once they fell into collapse, and died soon after. One of these shewed sanguineous congestion and extravasation in the brain. Have verified almost all the remarks made by Dr. Laurie, in his paper published in the Medical Gazette*. Quina used in the latter stages of the fever, on the same principles as occasionally adopted in typhus.

The admissions, 256—Deaths, 123; many of these moribund, when admitted.

* Dr. Symonds will perhaps be amused by the perversion of his reference at this place in our *honest* contemporary: our very name is "wormwood" to him.

ANALYSES & NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

Medicinische Zeitung. Herausgegeben von dem Verein für Heilkunde in Preussen. Berlin, Sept. 1832.

A SOCIETY of Physicians has been lately formed at Berlin, under the title of "The Prussian Union, for the improvement of the Medical Sciences," the object of which is, to lay before the world an account of what Prussia shall do for the advancement of medicine, and the sciences connected with it.

To accomplish this purpose, and to awaken a common feeling for the scientific improvement of the profession amongst its members, the Union has commenced a *Medical Gazette*, to be carried on weekly by the united efforts of all its members. The subjects which it embraces will be arranged under the following heads:—

1. Notices of the medical treatment adopted in the different clinical schools, and other institutions for the cure of the sick, in the kingdom of Prussia.

2. The scientific results of the practice of all Prussian physicians.

3. Notices on Anatomy, Physiology, Pathology, and Natural History in general.

4. Accounts of prevailing diseases, affecting men or animals.

5. Accounts of new remedies, and modes of treatment.

6. Cases in Medical Jurisprudence.

7. Materials for the medical topography and statistics of the Prussian states.

8. Descriptions of mineral springs and baths.

9. Meteorological registers; and the influence of the state of the weather on the general health.

10. Government regulations, as far as they are of general interest to the profession.

11. Medical obituary, appointments, &c.

12. Bibliographical notices of the most recent medical publications, foreign and domestic.

Without stopping to praise a plan so well calculated to improve the character of the profession, and to promote the advancement of science, we proceed to notice a few of the most interesting

communications in the four first Nos. of the Gazette, now lying before us.

Auscultation during Pregnancy.—In the first No., published Sept. 5, 1832, we have some observations by Kluge, Professor of Clinical Medicine and Midwifery, on the use of auscultation during pregnancy, which lead to the following conclusions:—

1. At the part of the uterus to which the placenta is attached, a rustling noise, isochronous with the pulse of the mother, is heard.

2. At the part of the uterus, which corresponds to the back of the child, a double beating is heard, varying from 120 to 180 strokes in a minute; this is louder in strong children—heard at different points when there are twins, and is wanting when the child is dead.

3. The placental noise is not heard distinctly till the fifth, and the double beating not till the sixth month.

4. Towards the end of the pregnancy the placental sound loses in intensity, that of the double beating increases, but the frequency is diminished from 180 to 120 in a minute

5. Before each pain, the double beating becomes more frequent and irregular, so that its approach can be predicted by this phenomenon.

Action of Acids on the Blood.—The next paper in this No. which we shall notice, is an account by *Hertwig* of the action of acids on the blood of living animals.

The author found, by repeated experiments with sulphuric, nitric, muriatic, carbonic, acetic, and tartaric acids, performed on domestic animals and birds at the Royal Veterinary School, that all these acids, with the exception of the nitric, produce a dark colour of the blood, both in the arteries and veins. The carbonic acid, and also the vegetable acids, produced a greater effect than the mineral ones. When the acids were introduced into the blood immediately, by injection, the whole mass of blood became darker in a few seconds; even in cases where death did not follow.

Prussic acid, in moderate doses, had no effect on the blood; but when given to an extent which produced difficulty of breathing and dizziness, the blood became at once black, and sometimes even of a tarry appearance. The instant that this acid began to act, the mucous membrane of the nose, tongue, gums, and lips, assumed a dark red colour.

Remarks on the Secale Cornutum.—In No. 3. several experiments made by Professor Kluge to determine the real effects of the secale cornutum, and discover the origin of the discordant opinions regarding its powers, gave the following results:—

1. The spurred rye, collected by the hand a few weeks before harvest, was alone possessed of activity; that separated from the winnowed corn being totally inert.

2. The use of the rye in women of a phlegmatic temperament, and in whom the pains had never been violent, or in cases of cramp of the uterus, often rendered the application of the forceps unnecessary.

3. In plethoric and irritable women, where the pains had been at first too violent, and had then ended in exhaustion; though the remedy did not produce contractions of the uterus so as to supersede the use of the forceps, yet it still proved a powerful means of preventing the flooding, which generally follows in such cases.

4. Given to the extent of 30 to 60 grains (10 grains to the dose, every 10 minutes) it never produced uneasiness in either mother or child.

It should never be given till the os uteri is fairly dilated.

Ossification of certain Muscles.—In the same No. we have a curious account, by Hasse, of ossifications, occurring in the substance of the pectoralis major, and tendon of the deltoid muscle of the left side, in the Prussian infantry recruits, amongst whom it is very common, and generally goes by the name of the "*Exercise Bone.*" Of 600 recruits, one half of whom had been one year, and the other half six months in the service, Hasse found 18 with the disease, more or less developed. He does not find the weak and cachectic more disposed to it than those of opposite conditions.

A few days after the commencement of the system of exercise, those pre-disposed to this disease, perceive a small red painful swelling on the part of the left shoulder, against which the musket leans. If this is neglected, a number of hard, moveable, gland-like tumors are formed in the muscle; these soon change into large masses of a solid cartilaginous consistence; and, lastly, in a period of from four to seven weeks, after the first feeling of uneasiness, the whole tumor is changed into a solid mass of

bone, which, according to its extent, impedes more or less the motion of the arm, and often renders the excision of the bony tumor absolutely necessary.

The pieces of bone extracted have been from three to five inches long, and from one to two broad, weighing from ʒiiss. to ʒi. Their surface is irregular, presenting small processes of bony matter. Occasionally the process was not finished; and the various changes of the red muscular fibre, in one part, into a tendinous shining mass, and in others into cartilage, which presented points or masses of bone of a regular cellular structure in different parts of its substance, could be observed.

Properties of the Cainca Root.—We shall close our notice of this Gazette for the present with a paper, by Albers, in the fourth number, on the medicinal virtues of the Cainca Root.

The favourable account given of this substance, as a diuretic, by François, (Journ. Général de Médicine, Mai 1830,) induced the author to try it on a great number of dropsical patients in the Charité, at Berlin.

The rad. caincæ, called by the Brazilians "black root," (*raiz preta,*) is, according to Martius, the product not only of the *Chiococca racemosa*, but also of the *Ch. anguifuga* and *densifolia*. Its taste is bitter and sharp; its smell nauseous. Administered internally, it produces nausea, and even vomiting, purging, and an increased secretion of the urine and menses. François asserts that it diminishes the frequency and violence of the heart's action, in hypertrophy of that organ. Spitta, on the contrary, found that it raised the pulse, and caused congestions. Langendorf and Martius speak principally of its purgative and emetic qualities. François, Kapeler, Bully, &c. though they admit these qualities, lay the greatest stress on its diuretic powers, and maintain, that if it act on the bowels, it is always mildly, and without griping. The doses are ʒij. to the 6 or 8 ounces of infusion or decoction; from 4 to 20 grains of the extract; ʒj. to ʒij. of the tincture; and 20 to 60 grains of the powdered bark.

Of 19 cases of dropsy treated by this root, 5 only had increased secretion of urine, followed in 4 cases by complete cure; but in these the collection of water was confined to the abdomen and legs: there was no organic disease or symptomatic fever. In the other cases, the medicine had no effect on the kidneys or on the dropsy; but, in 12 instances, produced such a diarrhœa as forbade its further employment. Most patients complained of nausea, and a few of vomiting and griping. It was also given in considerable doses to a patient labouring under disease of the heart; but, as it rather increased than allayed the palpitation, its use was given up, after 260 grains had been taken. It was also given to two healthy men, in very large doses, when it caused two or three stools daily, but produced no change in the quantity of urine. From these experiments, Albers joins his countrymen, Langedorf and Martius, in denying its diuretic powers, and placing it amongst the drastic purges, by the side of the Helleborus niger.

The names of Burdach, Kluge, Wolf, Becker, and other men of celebrity, which already appear amongst the contributors, are a sufficient guarantee for the accuracy of the communications, and for the talent with which this work will be conducted.

MEDICAL GAZETTE.

Saturday, October 27, 1832.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."
CICERO.

MEDICAL REFORM—EDUCATION.

One advantage that would arise from the sound general preliminary education upon which we last week insisted, would be the superseding of the apprenticeship system. The advocates of that system are fond of contemplating it in the light of a discipline similar to what the students of our universities are subjected to, or of the subordination which exists among the several ranks in the army and navy; and they flatter themselves that this analogy which they fancy they have discovered, gives them the best of the argument. To us, however, it seems to be nothing more than a fallacy. With regard to the army and navy, men enter them expressly to

serve; and discipline is practised there, not for discipline's sake, but that those subject to it may serve the better: in other words, the service is not ordered with a view to perfecting those who serve, for another condition of life, when they shall have quitted their present state of discipline: the analogy, in short, so far as we can pursue it, if there really be any, is as obscure as it can well be. Nor is it much otherwise with the other fancied resemblance. There is surely no more analogy between medical apprentices and the students of colleges, than there is between the latter and any other apprentices whatever. The students in our colleges do not happen to be bound by indenture; they can disengage themselves when they will; they pay only voluntary obedience to their superiors; they have no menial services to perform; masters (in the unpleasant sense of the word) they have none; and the object of their discipline is to perfect them in that general system of education which they had begun before they entered. With apprentices it is just the reverse: obedience is "in the bond;" and the indentured individual, if his master be in general practice, is, in too many instances, obliged to spend a large portion of his time in the performance of drudgeries which any uneducated person could perform as well, and which, most assuredly, ought not to be imposed upon him. Is it fitting, for example, that youths who are supposed to be gentlemen should open the door to their masters' visitors, and this even when *the other servants* are in the way? Yet many an apprentice can bear us out in asserting that this is no imaginary case.

It is scarcely possible to form an adequate idea of the nature of apprenticeships from what we see of them immediately about London; but we know that a large proportion of them are passed at a distance from any school where either preparatory or professional knowledge can be acquired. "Such apprenticeships," says an able writer, "cannot but be considered as an arrangement in which the interests of those who are training to the medical profession, are sacrificed to the interests of those who are already engaged in its practice." Now if this be the state of things in which some can discover an analogy with the discipline of an university, we can only say that it must be of an extremely delicate kind; for it totally escapes our apprehension. At the same time, we are ready to do justice to the liberality and paternal interest displayed by many towards the young men entrusted to their care; but then we insist that they do this, not in consequence of the indenture system, but in spite of it.

It is far from being a pleasing office to us, to make so many remarks unfriendly to the system of apprenticeships—especially as they are unfortunately imposed by law upon the Society of Apothecaries—a body which has done so much for the improvement of medical education, and which objected so strongly, in the first instance, to the introduction of the said system into the Act, however boldly some of its members may at present stand up in its defence. Our object is merely to shew, that supposing apprenticeships *could* be abolished, any little advantages which they possess could be amply replaced, while their abuses would be happily got rid of. The grand substitute and remedy, in our opinion, for this, as well as for several other ills attending the present mode, are to be found in the thorough general education to be insisted upon before admission to the schools, and in the superior discipline to be observed within them.

To the preliminary education we have already pretty fully adverted, and, we trust, with all the emphasis that may be requisite for producing a conviction of

its necessity; but with respect to the improved internal discipline, we have still a few remarks to make. And in the first place we know of nothing more strenuously to be recommended than the practice of repeated *examinations* at different stages during the progress of the course. There is no method of teaching by which the attention of students is more effectually insured: those who from idleness shall neglect the opportunities presented to them, are thus made to perceive the necessity of increasing their exertions; and those whose inability to undergo these tests may prove to arise rather from want of capacity than of application, are by this means warned in good time of their deficiency, and may thus avoid the pain and disgrace of rejection. The grinding and cramming systems, in which the pupil is taught to answer a certain set of questions mechanically, like a parrot, would thus also be put down, and the result of the final ordeal be rendered tenfold more satisfactory.

Until the period allowed for the prosecution of medical studies in the schools be better arranged, it would seem idle to propose the introduction of new subjects—additional burdens, as they would be called—for the already *overloaded* student. But there is much wilful deception abroad in this respect. Formerly it was thought a wonderful thing to add chemistry to anatomy and surgery; but it was done, and there was still found time to spare. Other branches of medical science were subsequently added; and we have seen of late what extent and variety of discipline the Society of Apothecaries has been able to include within a two years' course. How long, after this, will the other corporations slumber and sleep? What excuse can they possibly make for letting themselves be so far outstripped—not only in zeal, but in positive action? The introduction of the intricate but important branch of forensic medicine by the Court of Examiners, was a bold but most praiseworthy step. How now will the alumni of the elder corporations feel when they henceforth come in contact with practitioners called in along with them, or over them, as medical jurists—men who have devoted time and money to the pursuit of medico-legal science, and who, from the consciousness of that fact, will be for assuming that superiority to which they shall deem themselves entitled? The consequence is quite palpable. The study of medical jurisprudence must be *generally* cultivated in the schools: where before it was optional, it must henceforth become imperative. And so, no doubt, it will be with all the other branches of science, which to the said Court of Examiners it shall appear good to adopt; and so long as they keep in mind that the means of the middling and poorer classes cannot afford a remuneration which warrants above a certain expenditure in qualifying for the office of their attendant, we shall not be found among the first to cry, "hold, enough." But before any addition be made, let the numerous articles which have been of late crammed into the medical casquet be first arranged and set in order; let the space be economized, and the time required for examining the contents not be unreasonably wasted. The truth is, that much mismanagement has occurred in the mode of disposing the several courses laid down for our medical students: the business of two years is crowded into the occupation of some twelve or fourteen months; and those who are idle almost half their time are the loudest in the cry that they are over-worked. But the Society of Apothecaries is not to be blamed for this; they could not at once revolutionize the whole system of teaching previously adopted in England.

In a valuable paper which Mr. Wat-

son, the Secretary to the Court of Examiners, contributed to this journal (see vol. ix. p. 430), it is proved satisfactorily with how much ease the work allotted by the Court can be performed in many months less than the time allowed, provided a judicious arrangement be observed. The writer shews that, during the first session, the labours of the student may be comprised in the employment of between three and three and a half hours daily—and, during the second session, of somewhat less than three hours—leaving the whole of the summer season in each year to be spent in little better than recreation and amusement! There cannot be a doubt but that much valuable time is thus squandered with a wilful waste: and here assuredly there is a special opening for a beneficial interference.

But not merely with reference to the fulfilment of the Society's regulations, but with a view to the profitable pursuit of medical study generally, is a better arrangement of the time spent in the schools rendered absolutely indispensable. It fully merits the best attention of all our corporations, to consider how the different branches of professional education should be entered upon with most economy and advantage: and in this regard, perhaps nothing would seem to be more desirable than that they should decide whether a *natural* order, in the succession of the courses, might not be profitably adopted. Dr. Thomson, of Edinburgh, has offered some valuable suggestions on this head, which, however, we would adduce as applying more particularly to the education of physicians. He thinks that in order to avoid extending the course of medical study to a period of six or seven years—yet without abridging the number of topics necessary to be embraced—" it would require the adoption, in this country, of the practice pursued in many of the continental universities, of having two sessions of five months' duration in the course of the year. The two intervening months would afford ample time to the students for relaxation: and, if necessary for the accommodation of the professors, the order of the classes might probably be arranged in such a way that no professor would be obliged, unless he were so inclined, to lecture during more than one session in the year."

There can be no reasonable objection made—that we can see—to the adopting of such a course; at least, it is well worth considering: and for this purpose we lay before the reader the details of Dr. Thomson's plan.

" During the *first* session, the student might be instructed in the elements of Chemistry and in descriptive Anatomy; during the *second*, in the Physiology of Human Economy, and in the Natural History of the three kingdoms—Zoology, Botany, and Mineralogy; during the *third*, in General Pathology, in Practical Anatomy and Chemistry; during the *fourth*, in Therapeutics or Materia Medica, and in Surgery, with a second course of descriptive Anatomy; during the *fifth*, in the Practice of Physic and in Clinical Surgery; during the *sixth*, in Midwifery and Clinical Medicine; and during the *seventh*, and *last*, in Medical Jurisprudence, with a repetition of the Practice of Physic and Clinical Medicine." " This arrangement," adds Dr. Thomson, " would leave *ample room* for attendance, at the proper periods, on courses of lectures on Logic, Natural Philosophy, and Moral Philosophy, where these lectures had not been previously followed, as well as for a repetition of attendance on any of the medical classes, according as inclination or occasion for it might suggest*."

We can very well conceive that the perusal of the preceding extract is calculated to astound some of our medico-political economists: but we would en-

* Life of Cullen, vol. i. p. 666.

treat them to familiarize themselves betimes to the subject; for if physicians and surgeons would retain by right the ground which is assigned to them by courtesy, to some such measures must they come at last. The business of medical reform, in matters especially relating to education, being once begun, there is no knowing to what useful and excellent lengths it may be pursued. That there is "ample room and verge enough" for the work of improvement, none but the most sceptical can doubt: that it is full time for those in authority to bestir themselves, all the world is aware, and expecting what they shall do: that, when once at the work, those functionaries will not exert themselves with sincerity and zeal, none but the factious will venture to assert: but that they will act to the full extent that their powers of efficiency afford, and, as it appears to us, their duty requires, remains to be proved. We await the event in anxious expectation; but not without the hope, that, when they once commence the improvement of the present system, they will "reform it altogether."

SCIENTIFIC BISCUITS.

THERE is no end to the applications of science made by our Gallic neighbours. We mentioned last week that one of them, by his own showing at least, had discovered how to manufacture the finest wines from potatoes; and to-day we find that the members of the Academy of Sciences have devoted their labours and their knowledge to a subject of no less importance than that of making pastry.. It appears that a certain M. Gondolo, henceforward the most celebrated of pastry-cooks, has invented a new kind of biscuit, which has excited a very lively sensation in the French capital, especially among connoisseurs in the gastronomic art: they are called by the euphonious appellation of Griccini biscuits, and are of extreme lightness—lighter than an *omelet soufflé*,—in fact, as light as the heads of those who have recorded their excellence in the archives of the Royal Institute of France! Will it be credited that this momentous subject was disposed of, after only two reports, by a committee of the members, and but three discussions devoted to receiving the collective wisdom of the whole Academy! This gigantic labour of "the first scientific body in the world," however, was not without a correspondent progeny. It was moved by no less a person than M. Desgenettes, and at the end of the third deliberation agreed, "That the Academy declare the biscuits of Griccini to be very good biscuits, and fit to compete with any others of the same sort." If the Academy ever attach a motto to the reports of their proceedings, we would respectfully remind them, with reference to the present occasion, of the significant line—"*parturient montes*," &c. The saying is rather musty, but so, we suspect, must the biscuits have been—at the end of three weeks.

SINGULAR FORM OF CONVULSION.

AMONG the manuscripts of M. Dance was found one containing the following curious case:—A young man, aged 22, of respectable connexions and regular habits, came to Paris in 1825, to consult the faculty about his health. He had the appearance of being quite well, but was subject every day to a convulsive paroxysm, which consisted in the right hand striking the thigh of the same side, and then crossing the chest to the left shoulder; at the same moment the left hand played the counterpart of its fellow. This double set of movements was performed with such amazing rapidity, that at first they could scarcely be followed by the eye; gradually, however, they relaxed a little, and at length ceased for a moment, when the patient would sigh deeply, and begin again. Three such paroxysms generally took place in each attack, and lasted about five minutes each. Sometimes he was seized in the street, and then those passing supposed he was desirous of attracting notice. There seemed, however, no reason to doubt that the movements were altogether involuntary—probably analogous to those of St. Vitus's dance.

HOTEL DIEU, PARIS.

CLINICAL REMARKS ON THE QUESTION—CAN THE CHILD PASS THROUGH A CENTRAL LACERATION OF THE PERINEUM?

By M. Dupuytren.

Not long ago rather a stormy discussion took place at the Academy of Medicine on the results of a central laceration of the perineum. M. Moreau gave numerous cases of the accident, and a history of its consequences; while M. Capuron, the celebrated accoucheur, took occasion to deny *in toto* the possibility of the occurrence. It was probably this circumstance which induced M. Dupuytren to choose this for the subject of a clinical lecture-extraordinary which he delivered on the 16th instant. He began by reading the following case of

Natural Presentation—Laceration of the centre of the Perineum—Passage of the Child and Placenta through the aperture.

Madame Bourgillon, a cook, aged 38, of middle stature and symmetrical formation, but rather dry fibre, married about a year, and pregnant for the first time, was taken in labour on the morning of Sept. 8, 1832. At first the pains were slight, but became more intense towards mid-day, the head of the infant presenting in the "first position." The labour proceeded briskly, and was not retarded until the occiput arrived at the external fissure, which was extremely narrow. There then took place several sharp pains, during which, according to the account of the midwife, the vulva was dilated to the extent of about an ordinary drinking-glass, (*verre à boire*) when the forcing effort ceased, and the head receded. The midwife now lubricated the parts with oil, keeping her hand on the perineum, in order to support it. At a quarter to 4 o'clock, there came on, quickly after each other, two very violent pains: she felt the perineum tearing under her fingers, and the head, followed by the body of the infant, was straightway expelled through the laceration. The cord was tied and cut, and the child handed over to an attendant: the cord was now hanging from the artificial aperture, and the placenta speedily passed by the same route. No hæmorrhage took place. The infant was of the medium size, and is thriving well.

In her first alarm the midwife sent for M. Baudelocque, but seeing that Madame B. was not suffering, and that there was little remains of the rent to be perceived, she merely told him that the labour was over, without alluding to the accident, and resolved to let the first nine days pass over before she informed her patient.

Every thing went on well for two days; but a clyster which was then administered having immediately returned, without the patient having any power of retaining it, led to the apprehension of the sphincter ani being ruptured: it was even supposed that a portion of the clyster had returned by the wound. It was now necessary to acknowledge what had happened: however, some further time was allowed to pass without surgical aid. Castor oil was given, to keep the bowels open freely, and get rid of the milk. The babe was sent to a wet nurse, and the mother had little fever, or other symptom, except copious perspiration.

On the tenth day M. Guersent, jun. was consulted. He first tried very dilute lotions of chlorine, then touched the parts with caustic, and finally brought the edges of the wound together with sutures, the ligatures being supported by two buttons of gum-elastic. At the end of four days union seemed to have taken place, except at one small fistulous point next the rectum. The sutures were removed, and the adhesions seem to have continued two days, but were then destroyed, during some effort made by the patient. On the 6th of October she came to the Hôtel Dieu. The most scrupulous examination was then instituted into the causes and consequences of the occurrence. The patient, as already stated, was found to be well formed; the upper brim of the pelvis had the ordinary dimensions: the sciatic tuberosities had the usual distance; and the other parts presented nothing which appeared calculated to produce such an accident. As to the soft parts, the vulva remained entire, without any laceration at the fourchette, and was still narrow—the patient stating that the approach of her husband still produced pain. It is proper to remark, however, that the uvula is turned forward, being situated very close to the arch of the pubes, so that there is about an inch and a half between the posterior commissure and the anus. At this time four weeks had elapsed since the accident, and the tumefaction had subsided, leaving the parts in their natural state. The wound began four lines from the vaginal commissure, running backwards on the raphe to the extent of nine lines, and then falling at right angles into a transverse rent of six or seven lines, giving to the whole somewhat the form of the letter T. The measurements were taken when the parts were left undisturbed, but if the wound be stretched the dimensions become much greater: M. Dupuytren introduced three fingers without the slightest difficulty. The opening was continued perpendicularly upwards and between the rectum and vagina. No injudicious expedients

had been had recourse to during the labour, and M. Dupuytren had always considered the midwife a skilful one: she had practised four-and-twenty years. The patient had been placed nearly in a sitting posture during labour.

After this minute description of the circumstances, observed M. Dupuytren, there are two objections to be considered. The first relates to the doubt expressed by M. Capuron of the possibility of such an event. This gentleman says, that before yielding his belief he would require to know the size of the child's head: but if it be admitted that a small head might pass, the question is answered, for who will say that in parts so distensible a larger head may not pass when a smaller one has gone before?

The second argument consists in explaining the facts brought in proof of the event, by giving to them a different signification. Thus Mad. Lachapelle, before M. Capuron, had held that in every case of central rupture of the perineum the infant does nevertheless pass by the vulva, and she was wont to cite numerous instances in support of this doctrine. But this only shews, what every one must admit, that the perineum may be torn, though the child is born in the natural manner. That this may often happen, is granted; that it happens always, is inadmissible. Here is a case in point, with every circumstance to render it conclusive; and yet when M. Coutouly—a name honoured in science, related a case of this description, it was said he had lost his senses—he had been agitated—he had not seen. But if such a man did become agitated, assuredly it must have been after, not before the accident which affected him. But is it really so marvellous? To my mind the wonder is, not that it should occur sometimes, but that it should happen so seldom. Whoever has witnessed first labours, in which the vulva has so much difficulty in dilating, and the perineum so much disposition to become stretched, must have felt some apprehension lest the head should burst through it. It may be asked how—the supposed passage having been formed—the laceration does not extend into the vagina and rectum. But the *how* matters little; the fact speaks for itself. We might as well inquire how in this case, for example, the head passing by this so narrow vagina, respected the thin commissure which separates it from the wound? I am convinced that this passing of the head by the perineum is not so rare as experience would seem to shew, merely because the commissura vaginalis being ruptured, the accident receives the name of laceration of the fourchette. This leads us to inquire into the circumstances which favour an occurrence which is acknowledged to be uncommon; and the first point we remark is, that it takes place exclusively, or nearly so, in first labours. This patient, as has been seen, had the vulva turned forward. This arrangement is very remarkable, and too little known, in persons otherwise well formed, and who have not borne children. The vulva is sometimes situated forwards, and very near the pubes; sometimes very near the rectum, and looking downwards. It may easily be imagined how much, in the former case, the difficulty of labour will be increased, the vulva being only capable of extending itself backwards, and the head of the child having a longer traject to make; besides which, it is constantly pressing upon a perineum which extends more and more before it. At the very first examination this distention of the parts struck me in our patient; and accordingly the wound was found to be in the centre of the perineum, in the situation and with the direction which the natural passage has in other women. The position given to the patient appears also to have had great influence; she was so much supported by pillows as to be nearly sitting. This is in accordance with other analogous facts; in one such, for example, it is stated that the child was expelled through the perineum while the mother was sitting on the close-stool. Now it is clear that in such a posture the combined efforts of the uterus and abdominal muscles bear down with the greatest energy upon the perineum, and consequently that the patient ought to be placed horizontally.

Is blame to be attributed to the accoucheur for neglecting to afford due support to the perineum in such cases? In fact, the effort by which the child is expelled appears too energetic to be controlled without danger by external pressure. M. Contouly supported the perineum very powerfully in such a case, but without success. M. Evrat makes the same statement; as does Mad. Lachapelle.

On the second day, as above stated, a lavement could not be retained. As, however, it is ascertained that there is no communication between the rectum and vagina, this was probably owing to paralysis of the sphincter, which frequently lasts several days after delivery. Why did not M. Guersent succeed in curing the wound, as union had begun? Assuredly because he removed the ligatures too soon. In recent wounds reunion may be accomplished in four or five days, but in those which have gone on to suppuration—unless the granulating process be established, and favourably, a much longer time is required. Still more does the remark apply to a wound of this nature, where the adhesion is further retarded by lochial discharge. I have many times (said M. Dupuytren)

had occasion to unite by suture suppurating wounds, and I have found that the process required twice as long as in recent wounds, and more than this under circumstances like the present. I was called by M. Gardien to a young girl put to bed clandestinely: the labour had terminated in a complete rupture of the perineum, which reached as far as the anus. Many days had already elapsed, and I introduced sutures at separate points; but now I should prefer the uninterrupted form. At the end of a month the girl was obliged to return to her father's, and the union was not then complete, obstinate suppuration having been the only obstacle—for I had not cut the threads, and they had not worn through the flesh. I recommended that the sutures should be left, thinking union would yet take place: this was done, and I heard nothing more of the case at that time.

Three or four years after, I saw a man and woman enter my consulting-room, the latter keeping behind, and making me a sign, to be prudent. The man—he was her husband—informed me that he had not been able to consummate the marriage, and he wanted to know whether the fault lay with him or his wife. I examined her, and found the opening of the vagina very narrow, and turned forwards: the perineum displayed a long and firm cicatrix. I advised the husband to renew his efforts, which were at length crowned with success: the woman became pregnant, and was delivered without any fresh laceration —rather a remarkable circumstance. This was the patient on whom I had operated several years before, and she informed me that the medical man who afterwards saw her left the ligatures undisturbed, till perfect union had occurred.

In most cases union will occur spontaneously, under the assistance of rest and cleanliness: in the present instance, however, that cannot be expected, for the edges are partly cicatrized. Now here lies the doubt: ought reunion to be attempted, or the septum between the wound and the vulva be divided? By this last proceeding a large orifice would be formed for the vagina, which would be attended with no inconvenience, while it would greatly simplify the matter. To effect reunion fresh edges must be made, the uninterrupted suture applied, and suffered to remain as long as it produces no mischief. By this means would be produced a very narrow aperture to the vagina, and that turned forward, so that on a second accouchement the same difficulties would occur as before, increased by the less extensibility of the perineum. The subject must be duly weighed before we come to a decision.

CHARLES HENRY ADAMS.

NOTICES.

Communications have been received from the following gentlemen, to whom we have to apologize for postponing their papers till next week, in consequence of some of the articles in the present No. having proved longer than was anticipated; but having been advertised as forthcoming they necessarily received the preference:—Dr. George Burrows, Dr. Osborne (Dublin), Mr. Estlin, Mr. Beddome, Mr. Dade, Mr. Braithwaite, G. H. (Margate,) "W." "Cantus." The circumstance alluded to has also rendered the omission of the analysis of Mr. Lindley's Botany unavoidable, though mentioned in the advertisement.

MR. BARBER.—The "Inspector" addressed a note to us stating that students were not required to take out a license for dissecting at a licensed school.

W. WILSON, Printer, 57, Skinner-Street, London.

LECTURES

ON THE

THEORY AND PRACTICE OF MEDICINE;

Delivered at the London University,

By Dr. Elliotson.

EXANTHEMATA.

Scarlatina.

I MENTIONED, gentlemen, that there were three varieties in scarlatina: one in which the general symptoms are mild, and the throat scarcely at all affected, called *S. simplex;* one in which the throat becomes much affected, not being altogether inflammatory, though perhaps violent, and called *S. anginosa;* and one in which the surface, and the whole of the system, are violently affected, the disease having a typhoid character, and the state of the throat being of a gangrenous description, and called *S. maligna.*

S. maligna.—We sometimes see this latter form of the disease occurring generally throughout a neighbourhood, at least generally during an epidemic; sometimes we see one person affected with it in a neighbourhood, while other persons, or children, are affected with other forms of the disease. Sometimes, even in the same house, you will see all these various forms of the disease. It appears, therefore, that the causes of the disease putting on this malignant character, are sometimes something general in the state of the season or place, and sometimes something altogether dependent upon the condition of the individual: it does not appear to be any thing peculiar in the contagion. We shall find, in the case of small-pox, that matter taken from a person labouring under a mild variety, will sometimes give a malignant, confluent, violent form of the disease, in another. So in scarlet fever, the mild form of the disease is sometimes caught from a person labouring under a malignant form, and *vice versâ;* and although one while we see numerous cases of malignant scarlatina during one particular epidemic, and especially in a particular neighbourhood, yet at other times we shall see the malignant form occur sporadically. It may occur only in one individual or two in a neighbourhood, while the rest have the mild, or merely the inflammatory form; and we even sometimes see this peculiarity cease in one place, and another become filled with the inflammatory or mild form. I believe that the malignant form is more common in winter than at any other period. The circumstances that give rise to it are not well known.

There is, however, another form of the disease, in which the throat is affected, and not the surface. Some, indeed, have denied this, just as some have denied that measles is occasionally seen without catarrh. As, however, this disease affects both the surface and the throat, and as some have asserted that it frequently affects the surface while there is little or no affection of the throat, so there is no reason whatever why the throat sometimes should not be affected, while the surface is scarcely or not at all affected—while there is nothing upon the surface worthy of the name of an eruption. Dr. Willan mentions, that in epidemic scarlatina, there are always many cases where the throat only is affected, and that these cases will communicate all forms of the disease just as if the skin were affected. This, I think, is not at all surprising. In that form in which the throat particularly suffers, if we were to look over the skin from head to foot two or three successive days, we might discover in those cases an eruption; however, it would be so little, that we should be almost justified in saying there was none; and I

have seen several in a family affected with the sore throat only, and that mildly.

Those who formerly had scarlet fever, and even those that are recovering from it —those who are convaleseent, only just getting strong—if they be exposed to the contagion again, will sometimes have a little soreness of the throat, and even patches, induced by the contagion.

Treatment.—The treatment of this disease is for the most part very simple. If you take eare to do the patient no harm, he in general will do very well. In this disease cleanliness and fresh air should be particularly attended to. If the season will allow it, the windows and doors should be opened, and the slightest covering placed upon the patient. Cold drinks, and water, or something nearly as simple as water, are the most eligible. No food beyond this, except it be milk and water, should be allowed. The bowels of course should be kept open. It is said that you alleviate the disease if an emetic be given early in it; some are of a different opinion, but many contend that at the beginning of the disease it is very good. The disease certainly has been cut short by taking a patient out of bed and pouring cold water upon him. The heat of the body is so great in this disease that no danger is to be apprehended from cold affusion. It is true, there are cases in which the patient is more or less chilly; but if, in this affection, the general rules be followed which I laid down in the case of common fever—that is to say, if you observe the temperature is steadily above 98 degrees, if there be no profuse general sweats, and no sense of chilliness, however hot the patient may be, and if there be no decided inflammation of the chest or abdomen—there is no danger whatever, but the greatest advantage, in taking him out of bed and pouring cold water upon him. I presume this would be done oftener than it is, were it not for it appearing a violent measure, to take a person, with fever, out of bed, put him into a washing-tub, and souce him well with cold water. But at any rate no friends will object to your washing a patient with cold water, and it is a great comfort to the individual, and as long as it is comfortable it should be had recourse to. Sponging the hands, arms, face, and trunk, with cold water, is grateful to the patient, and is an excellent practice in the disease.

If the inflammatory symptoms run high, of course it will be necessary to bleed in the arm; but in general it is only requisite to give the patient fresh air, to give him little better than water to drink, nothing to eat, keep him clean, let him have but few clothes upon him, and keep his bowels open.

But if the symptoms should be violent, that is to say, if the head be affected, (you will recollect I mentioned, that occasionally in this disease very violent phrenitis will come on,) if any local inflammation come on in the head, chest, or abdomen, it may be necessary to take blood from the arm. You are not to neglect local inflammation, because the affection under which the patient labours is scarlet fever. For the most part this inflammation may be subdued by local bleeding, and it is best to remove it by local bleeding, if you can, because you produce less debility than if you take it from the arm with a sudden shock. The case, however, it is to be remembered, may be so severe as to render general bleeding imperative.

The chief parts that suffer in the disease are the throat and head: the throat, of course, because it is one of the seats of the disease, and the application of leeches around it is exceedingly useful; far better than a blister, as I shall mention when I come to speak of common sore throat. In that affection blisters are frequently very severe, but leeches afford immediate relief, and plenty of leeches about the throat or about the head are often valuable in scarlet fever. You may see the tongue particularly foul in this disease, and that might make you imagine that there was a great disturbance of the digestive organs, and therefore that emetics, calomel, and things of that description, were particularly necessary. But this, I think, is a wrong inference, because the tongue is one of the seats of the disease. It is not foul because there is intense feverishness of the system, but foul because it is in a state of inflammation. It is, as I have said, one of the parts which the disease affects; you see the papillæ exceedingly red, the tip is red, and the secretion on the back of the tongue is diseased in quantity and quality, and you may have, in fact, besides the redness of the papillæ, just such a tongue, with respect to the dorsum, that you have when a person is fully under the influence of mercury—a tongue covered with a yellow white thick mucus. The tongue itself is swollen.

You will find the state of the mouth much alleviated by allowing the patient cold drinks, or, if it be agreeable, he may have them iced: for the heat of the throat and mouth is very great.

However, you will see sloughs continually formed upon the throat. I believe I mentioned that it is not every thing which looks like a slough that is one, because the disease produces the effusion of shreds of lymph, and they lie there as though it were a little ulcer; but occasionally you have ash and dark coloured specks, which you find cannot be easily removed, and

which are neither more nor less than so many sloughs; and in the malignant form you have very considerable sloughs. These, whether they be mere shreds of lymph, or sloughs, are always best treated by gargles of the chloride of soda or lime. The more intense the gangrenous tendency, the stronger must be the gargle. In ordinary cases of scarlatina, a gargle, composed of two ounces of the common solution to half a pint of water, is found enough. This will produce a pricking sensation, and is even sometimes too strong; but, in other cases, where the sloughs are very considerable, you may employ it much stronger than this. In the merest specks of the throat, you find this one of the best applications that can be employed. However, you frequently find a difficulty in the application of gargles, and it is better to use a syringe, and squirt the gargle at the throat, and if any of it be swallowed it is a good internal medicine, and will do no harm. I know no gargle to be compared with a diluted solution of chloride of soda or lime, both in cases of scarlet fever and in cases of thrush.

If the disease shew a very considerable gangrenous tendency in the throat, if the pulse be very soft and feeble, you have only to treat it, generally, as you would treat any case of typhus fever. Among the internal stimulating medicines, which it is found necessary to give at the last, carbonate of ammonia is one of the best, with the exception, perhaps, of wine, which generally answers better than any thing else. Patients will sometimes take a great quantity of wine in this disease. Dr. Withering, who wrote on this disease, says, that in an epidemic which prevailed among a number of children, about twelve years before he wrote, each must have taken a bottle of the best port wine in 24 hours, for several successive days; wine is borne, on these occasions, which would intoxicate and destroy at other periods: but the treatment would be the same as for typhus fever, where there was great debility, or a tendency to putrescency or mortification, independently of violent inflammation.

Some persons think that ammonia has a peculiar power on the disease, and they say they have given it in every case of every description, whether inflammatory or not, and that they never lost a case in their lives. I presume that the cases which these gentlemen treated were very few of a malignant character; and if they had given all the children a piece of sugar once in the twenty-four hours, still the greater number would have done almost as well. This is a disease for the most part which terminates favourably, if the practitioner does no harm, and a little ammonia can do no harm; but, by rational treatment, you make it run its course mildly, and prevent the patient a great deal of suffering.

If the eruption recede, then the best treatment is, to put the patient into a hot bath several times a day; rub the body with stimulants; and give stimuli internally. But here it is necessary, as in other similar cases, to observe whether an internal inflammation has come on: it may be that which prevents the patches from coming out, and in such a case you must be careful not to give internal stimuli. You would then apply leeches, to remove the internal congestion and inflammation. You may stimulate the surface at the same time; but the great point is to alleviate the internal affection, which prevents the external.

Prophylactica.—As this is a disease which children do not necessarily take as they do measles and small-pox, it is but fair to endeavour to prevent them from catching it; and, besides free ventilation and cleanliness in the house, the use of the chlorides may be proper, with a view of destroying the contagion. I do not know whether they do destroy contagion, because I have recourse to fresh air, plenty of water, and cleanliness; and as I feel it my duty to use the chlorides at the same time, it is impossible to say what is done by the one and what by the other, and I have no means, therefore, of drawing a conclusion. But it would be well to throw the dirty linen taken off a patient into water in which the chlorides have been introduced—to put the chlorides into various utensils which are used, and to sprinkle them about the room. In this way you may possibly prevent other persons in the house from catching the disease.

There is, however, a medicine recommended by a German physician for the purpose of preventing the disease, which, to me, appears of a very fanciful character. Dr. Hahnemann, of Leipsic, says that belladonna will prevent the disease. He says, that if you take two grains of the extract of belladonna, and dissolve them in one ounce of cinnamon water, or pure water, which is the same thing, and give two minims of this solution to a child a year old, or another minim or more according to the age of the child, you may prevent the disease. I never thought it worth while to try it, because I hardly think the observations which are published conclusive. I know that foreign physicians have since published accounts of the disease being so prevented, but it ought to be from hundreds of observations that any one says the disease has been prevented, because it is an affection that will not attack every one in a house; and every now and then, when the disease has been spreading for some weeks, all at once it

will disappear, and no other persons have it. Inferences, therefore, ought not to be drawn without very, very numerous facts—numerous coincidences, well ascertained.

In regard to the anasarca which follows this disease, I have no doubt that it frequently arises from cold, because it begins in the face, or the face is particularly affected as soon as any other part. It may be attributable to exposure to cold when the disease is over, or declining, because it is an affection that does not take place during the disease, but subsequently to it. Rayer condemns the application of cold in the disease, because it is likely to produce anasarca. Now I have used cold ablution, not affusion, generally in this disease, and I never had a case of anasarca in my own practice which occurred when I myself had treated the disease. I do not believe that, if low temperature be properly applied—that is to say, when the heat of the body is too great—that there is any danger of the patient catching cold; but if it be used when the patient is not hotter than he should be, or after the disease has declined, then I have no doubt that it would lead to anasarca. However, this anasarca appears to be inflammatory; and for this reason it resembles the anasarca which is the effect of exposure to cold, especially cold and wet united. It begins in the face, or it particularly affects the face, or it is seen in the face as soon as any where; and, in the next place, the urine is often albuminous, and it will not merely contain albumen, however, but sometimes blood. In most cases of anasarca which I have seen, (perhaps I have seen them only because they were intense,) there has been more or less internal inflammation, in some degree or other, usually in the head, chest, or abdomen, just as in acute anasarca from cold, but in almost every case in the chest; sometimes peripneumonia or pleuritis.

The treatment of the anasarca is best conducted by antiphlogistic means; purging the patient well, which is an antiphlogistic method; and some say by giving digitalis; but I know that it recedes best by purging, and by attending to any internal inflammation that may exist. It would be in vain to purge in severe inflammation of the chest, unless you made use of leeches at the same time; and the same remark applies to the head. It is important in all these cases of anasarca supervening on scarlatina, to examine whether there be inflammation, for if you neglect that, the anacarca will generally be tiresome; but if you treat that, it will go away. Occasionally the anasarca goes away of itself, but you may always expedite it by purging, or by applying antiphlogistic measures pretty briskly directed towards some internal part.

I do not know whether it is mentioned by any author, but, besides phrenitis or arachnitis, rheumatism is not an uncommon sequela of scarlatina.

Erysipelas.

The next disease of which I will speak, is one that I hardly know where to place—I mean erysipelas. Rayer places it with the rashes, because there is a continuous redness of the skin; but Willan places it among those which have a large collection of water, bullæ. The truth is, this disease may exist without the formation of any secretion—without any collection of water, or even vesicles of water; yet I think that, in a great number of cases, it does produce an elevation of the cuticle, of smaller or larger size, containing water. Upon the whole, it may be right to place it with the rashes, as the redness is diffused, and it always exists, whereas vesicles or bullæ do not, but it is a matter of no very great importance.

Erysipelas is a very intense affection, of the same description that roseola and erythema are in a mild form. What roseola and erythema are mildly, this is severely. If you have a case of diffused redness of the skin, with heat and more or less smarting, and without disturbance of the constitution at all,—without any swelling of any consequence—you may call it erythema; or if there be no more, and the rash is rose-coloured, you may call it roseola; but if the part be much swollen—if the inflammation be very intense—if there be burning pain, and the heat be very great, or the constitution be disturbed—then you call it erysipelas.

Diagnosis of Erysipelas.—It differs from erythema in this (the inflammation of erythema may be chronic, as in E. nodosum or E. tuberculatum)—erysipelas is always an acute febrile disease, attended with heat and swelling, and pain (which erythema and roseola may not), by redness of some part or parts of the skin in patches, and it is often united with vesication. The swelling is irregularly circumscribed, and is generally soft. Generally the redness disappears on pressure, and instantly returns when the pressure is removed, as in erythema and roseola.

Symptoms.—Very often, before this inflammation comes out, there is a previous excitement of the constitution, as is the case in measles and scarlet fever. Before tenderness of the skin is felt the patient may be feverish, or he may have headache, nausea, vomiting, drowsiness, vertigo, tenderness of the epigastrium, or he may have rigors. After these symptoms have existed for some time, more or fewer of them, and in greater or less intensity, about the second or third day some part of the skin will feel

sore, and on being looked at it will be found a little swelled, a little red and hot; and then all this increases. The skin becomes more swelled, very red and very hot, and the patient experiences pricking or smarting pains, and the general feverishness, the pyrexia, the excitement, is increased. Occasionally the local symptoms appear first, the feverishness taking place exactly in the same degree that they do; but sometimes you have the feverishness first, and then the redness appears.

Very frequently, after a little time, minute vesicles are seen here and there, in the inflamed part. Frequently you have no vesicles at all; and when you have vesicles they frequently occur only in some particular parts of the red patches. Sometimes they are not very large—they are really vesicles—but sometimes they are as large as walnuts, and are called *bullæ* in Latin, and *blebs* in English. These contain at first a clear fluid; but sometimes, after a day or so, it becomes turbid, and is more or less yellow. These burst, and the fluid oozes, so that a yellow crust forms—a crust which is made of this dried secretion and the exfoliated cuticle. If the disease decline without forming any of these vesicles, or bullæ, then the cuticle is sure to come off, and you have a scurf; but if there be vesicles, or bullæ, then you have crusts. Sometimes the surface under the elevated cuticle, after the bursting of the bladder, secretes pus, more or less suppuration will take place, and sometimes the secretion, be it pus or mere lymph, is very acrimonious, so that it produces great irritation of those parts on which it goes.

Metastasis—Varieties.—This is a disease which has a great tendency to spread; it will sometimes spread over half the body. I have seen it spread from the occiput down to the toes. As it spreads, sometimes the part first affected recovers; at other times it does not, so that you have one immense sheet of red colour. It is very curious sometimes to see, as it spreads along, how the parts first affected become well. Now and then it will suddenly cease, and some internal part suffer. This change of situation is called *metastasis*; and if it solely disappears in one part of the surface, to re-appear in another, then the French call the circumstance *delitescence*; but if an internal part be affected, it deserves the name of *metastasis*. When it extends slowly from one part to another, whether the part affected recovers or not, it is called *E. erraticum*—wandering about. In another form you will observe sometimes very great swelling, and a great effusion of serum into the cellular membrane, and it is then called *E. œdematodes*, being œdematous. Now and then the irritation of the cellular membrane under the skin is much more severe than to secrete mere serum; it is so severe as to secrete pus, and then it is called *E. phlegmonodes*, it being the character of phlegmon to secrete pus.

When this occurs—when the cellular membrane underneath the skin becomes affected, as well as the skin itself, to a great degree—there is extreme pain, extreme tension, extreme hardness; the limb feels as though it would burst, the patient is skin bound, and the general symptoms throughout the body are excessively severe. Suppuration sometimes occurs only here and there, but sometimes it is very extensive. It is by no means uncommon, in partial phlegmonous erysipelas of the face, to see the affection suppurate in particular spots, as, for instance, at the orbit. The cellular membranes under the eye-lids is disposed to run into suppuration, when there is no suppuration in any other part of the face. But, besides this local E. phlegmonodes, you will sometimes see a whole extremity fall into this particular state.

Erysipelas is a disease which is by no means confined to the surface of the body: you will see the throat continually affected. If the inner part of the throat and mouth are the seat of disease, you will see the throat red, the tongue red, the mouth complained of by the patient as exceedingly hot, perhaps a short cough, and a difficulty of swallowing: in fact, there is a sore throat. Very frequently, too, it will run down the membrane lining the tubes, so that you have a very great cough and a difficulty of breathing. You have more or less bronchitis, and sometimes there is really severe bronchitis, but for the most part it is only a superficial sort of inflammation—erysipelas of the mucous membrane—which will go away without the adoption of any strong measures. Very frequently, besides the sympathetic effect occurring at the beginning of the disease, you find great tenderness of the epigastrium, the patient complaining of intense heat there, and sometimes the same is felt all over the abdomen, as if the inner surface of the intestines were in a state of erysipelas, and then you have diarrhœa. I have seen the disease spread down the air passages, and then down the alimentary canal. But, besides this spreading from the skin through the ramifications of the trachea and bronchiæ, and through the pharynx and œsophagus to the stomach and down to the intestines, you see the membranes of the brain continually affected, when the head and scalp are the seat of the disease. When the disease affects the inside of the head, which it is much disposed to do after it has attacked the face, neck, and scalp, the danger arises from inflammation of the membranes of the brain, so that you have, as the disease advances, extreme drowsiness; the patient complains

of internal pain of the head, delirium comes on, and at last there is more or less of an apopleetie s'ate. When the face is affected, from the general swelling and the effusion into the cellular membrane, the eyes are closed and the features are lost, so that you could not recognize the individual at all. The person becomes as ill-looking a blackguard, in his appearance, as can be conceived. His nose is bottled, and is buried in his cheeks; in fact, he looks as if he had been drinking hard, and had had a good drubbing. The features are set, the eyes closed, and there he lies not to be recognized by any one. I know this by my own ease, having myself laboured under the disease. My friends brought a looking-glass, and, on raising the upper eye-lid, I peeped at myself, but the sight was so abominable that I begged the glass might be removed.

Morbid appearances.—When the patient dies with symptoms of inflammation within the head, drowsiness and delirium, &c. shewing inflammation there, I have always found, certainly not inflammation within, but the effects of inflammation, effusion. I have always seen an effusion of serum in the brain—in the ventricles of the brain, or upon the brain, or in both situations; and sometimes great turgescence of the vessels.

The disease is very much disposed, in many cases, to produce mortification; parts of the skin will continually slough, the vesicles will become dark, and the fluid which is within them is bloody. But, besides that, the disease will frequently produce sloughing deeper in, and death will take place to all appearance from the gangrene. When this is the case it is called *E. gangræosum*. Infants are very liable to this gangrenous erysipelas: new born infants will frequently have it about the umbilicus and the genitals. I have seen this occur without any vesication at all. Round the umbilicus, or the pudendum, in young children and infants, the parts will become very red, very hot, and hard, the red will become dingy, and then gangrene take place, and the parts become perfectly black. This occurs very frequently in the extremities, but in the case of children it is about the genitals and the umbilicus that it usually takes place.

You see, therefore, that this is a disease exactly like continued fever, or any common inflammation, or exactly like scarlatina, the last disease which I mentioned: I mean it runs from mere active inflammation with strength on the one hand, down to the most perfect prostration of strength on the other, and the most violent tendency to mortification. It is, therefore, pretty evident that no one mode of treatment can be adopted; before, however, I speak on that subject, it will be right to mention what are the causes.

Causes.—The common causes of the disease are, vicissitudes of temperature, exposure to cold, especially when the person is heated; but it very commonly arises from some local cause—mechanical injury, or any thing that irritates. It is much predisposed to by certain situations. There are certain situations in which erysipelas is very common. There are hospitals, it is said, where erysipelas is more common than in others. It certainly appears to be dependent, in some measure, upon the season. At particular periods, in several hospitals in the same town, where all is healthy, all at once, where they have had no erysipelas, the affection will become very common. Besides the common exciting causes, such as refrigeration or local injury, it depends, in a great measure, upon local circumstances, and also on something in the air at the time. These circumstances may be so strong that, without any local irritation, patients will be seized with erysipelas, and the slightest local injury will sometimes do it. Erysipelas in these particular seasons, or in these neighbourhoods, may be followed by the most violent inflammation. Persons of bad constitution are also very liable to it. Those who have been in the habit of drinking spirits, or have ruined their constitution in any way, are very likely, from the least injury, even from leech bites, to fall into this disease.

Contagious (?)—It is said by some that erysipelas is occasionally contagious. Dr. Wells published, I believe I mentioned formerly, a number of cases to prove it contagious. It does appear in the cases he mentioned that it was contagious. The instances were numerous, and they were cases of persons who went to visit others who had erysipelas, and then went back and gave it to those in their own houses. I cannot exactly say that I have seen it contagious. I have seen, as I suppose every body has, in hospitals, patient after patient become affected in a ward; but whether it arose from local circumstances, or from emanations spreading from one individual to another, I cannot tell. I recollect once having had it, five days after stooping down over a patient who had the disease in so violent a form that he died of it. I was looking into the state of his skin, and his breath came into my face. I turned away disgusted, and said, "I hope I have not caught it;" but five days afterwards, having forgotten the circumstances, I was seized with it. I felt chilly, and my head was sore, and I had the disease violently; this was in the winter, when one is liable to catch cold, and therefore I am not sure that I caught the disease from contagion: only I never take

cold that I know of. I have seen instances where the affection might have been contagious, but I am not sure that such was the case. You will find Dr. Wells's cases in two volumes of the Transactions of a Society for the Improvement of Medical and Chirurgical Knowledge.

Treatment.—The treatment of the disease is self-evident. It must be totally different in different cases. In the country, and in young, strong, healthy subjects even in town, there can be no doubt of the propriety of taking away blood from the arm. I have often bled patients, and was repeatedly bled myself, and with the best effects. On the other hand, if a patient have a shattered constitution, either in consequence of being half-starved, or of intemperance, or any thing else, then you must employ bleeding with great caution; but still, in the greater number of cases, antiphlogistics are the proper remedies, though perhaps not carried to a great extent. Purging, and the other parts of the antiphlogistic plan, are necessary. I have always found cold useful (I employed it in my own case), and I never saw the disease recede in consequence of it. I never saw internal disease in consequence. The direct application of cold water, or by means of rags, is very uncomfortable to the patient after a time; and as soon as he says this effect is produced, it is but common sense to leave the cold off. If fresh air can be obtained, it should be had recourse to in this, as in most other diseases. You will frequently find local bleeding answer every purpose; but I should never shrink from general bleeding if it appeared desirable; there is nothing to fear from it. In regard to local bleeding, you may employ it by means of leeches around the part, or you may put them on the part itself. There is no harm in adopting the latter plan. I was not aware of this at one period, but I have tried it, and now I know it by experience. Some think it is more eligible to take away the blood by means of needles, or the point of the lancet, because there is not that irritation which is occasioned by the bite of a leech. I have never seen harm result from leech-bites, when they were applied to the inflamed part, or to the part itself; but it is said there *never is* any danger if you withdraw the blood by means of acupuncture. There is a vast collection of blood in the erysipelatous part; and if you puncture you may frequently unload it to a great amount. You will find that you may put a stop to the progress of the disease (I have done it times without end), by the application of the nitrate of silver. If you rub the nitrate of silver on the healthy part around the disease, or if you make a strong solution and paint all around with a brush, you will generally prevent its farther progress. Some persons recommend blisters, but the nitrate of silver answers perfectly well, and much better. I have stopped the disease over and over again by this means, and I should feel it right to have recourse to it in every severe case. We are indebted for a knowledge of its use to Mr. Higginbotham, of Nottingham. He has written a work to shew the good effects of this remedy, not only around the part in this way, but applied to the inflamed part itself. You will have fuller information on this subject in the Lectures on Surgery, than it is my business to give; but I know that you may stop the erysipelas in the way I have mentioned.

It is necessary, however, that the application should be continuous; for if you allow a small space at which the disease can creep out, depend upon it it will. I have seen cases where a portion was left, and I have seen the affection creep through there, and spread along the part.

It is very important to stop the progress of the disease if it be near the head, because if it should spread over the head, or even half over it, it is ten chances to one that you have delirium and inflammation of the membranes of the brain, and the patient will die in an apoplectic state.

If there be much tension in the part, there is no impropriety in doing more than emptying it by leeches; indeed, it is very important to make an incision in it by means of a lancet, and the tension will then sometimes cease immediately. It is in E. phlegmonodes that this is particularly required. Generally, if you take away blood, purge, starve, and apply cold, the disease will give way; but if there be this extreme tension, and you make an incision, the part immediately stretches, just as it would if you had made a slice in a shoulder of mutton. The practice is now, I suppose, well established. Some surgeons make the incision a foot long, but others make half a dozen incisions, each an inch in length—some doing it all at once, and others, as Mr. Lawrence once waggishly said, by instalments; that, however, is a matter of surgical choice. But of the use of making incisions for the purpose of letting out blood or pus, or before pus is formed, merely to take off the tension, by allowing the blood to ooze from the part, there can, I think, be no question.

In case mortification threatens or occurs, you have to consider whether it depends upon the violence of the inflammation. If the inflammation be violent, you must not, because there is mortification, give wine, bark, and opium, but strive to subdue the inflammation by antiphlogistic means. Again, if you see or fear a sinking of the

constitution, and even there be no mortification, then wine, porter, opium, and bark and good food, must be given, just as you would treat any common case of inflammation.

In doubtful cases, when you hesitate whether to bleed and put the antiphlogistic plan into force, or to stimulate and support, the best plan is to apply cold effectually, unload the part by leeches or punctures, and give beef-tea and milk and quinine. I have never seen quinine do harm, even in active tonic erysipelas; and in doubtful cases I believe it always a safe and eligible medicine.

LECTURES
ON
DISEASES OF THE EYE;

Delivered at the Birmingham Eye Infirmary,

By Richard Middlemore, Esq.

Introductory Observations.

I have only studied diseases of the eye as a part of, and in connexion with, my profession generally, yet having been for many years one of the medical officers of this institution, and having in consequence of such appointment annually witnessed nearly 1500 cases of ophthalmic disease in its various forms, I have felt that it is my duty to communicate any information my unusually ample opportunities may have enabled me to acquire.

In former times, the treatment of diseases of the eye was confined to persons assuming the name of "oculist," who very frequently acquired, with great notoriety, considerable wealth and importance. You will observe, that these persons were generally characterized by extreme assurance and extraordinary ignorance, and that their treatment consisted almost entirely in the rude and unscientific application of local remedies. If, however, by the term "oculist," is meant a person competent to treat the various maladies of the human eye, without any, or only a very slight, acquaintance with general anatomy, pathology, and therapeutics, we may confidently assert that there is no such individual in existence; for he only can be adequate to the treatment of disease, in whatever part it may be situated, who is conversant with the natural structure of parts, with the laws which regulate the healthy functions, and with the alterations produced by the encroachments of disease—with the sympathies, the influences, and the connexions, subsisting between every part of the animated machine.

You know that the treatment of an inflamed mucous membrane is essentially the same—the same in principle—in whatever part it may be situated, and that it would be altogether absurd to restrict the treatment of disease, in accordance with the situation of such disease, to certain individuals who professed to have especial qualifications for its treatment whenever it had fixed upon some particular district. You would at once assure that person who told you that he had confined his attention to the management of maladies of the eye, and was wholly unacquainted with those of other parts, that disease could not be judiciously or scientifically treated by one possessing merely his partial acquirements.

The eye has its sympathies with, its relations to, and its dependencies on the system, in common with every other single organ of the human body; it is also composed for the most part of the same materials, worked, in some instances, into *precisely* the same textures, which possess the same functional properties, as many other parts of the animal machine. So that it is altogether ridiculous and unnatural to attempt to separate this department of our profession from those other branches of it, with which it is so intimately connected.

Many of the greatest ornaments of our profession have written very ably on ophthalmology, as, for instance, Cheselden and Pott, the late Mr. Hey of Leeds, and Mr. Gibson of Manchester; and among the surgeons of the present day who have distinguished themselves by their writings in this department of knowledge, I may mention the names of Scarpa, Wardrop, Guthrie, Travers, and Lawrence. You will perceive, therefore, that a most intimate knowledge of ophthalmic disease is not only compatible with the ordinary pursuits of our profession, but is also materially assisted by the attainment of that information which none but the thorough surgeon can be presumed to possess.

The study of diseases of the eye is peculiarly interesting, for, in consequence of the superficial situation of some of its textures, and the transparency of others, you have frequently an opportunity of observing its respective maladies, and of actually witnessing the morbid process. When the pleura is inflamed you may infer from existing symptoms that serum is effused, that lymph is deposited, or that pus is secreted, as a consequence of such inflammation; but, if the conjunctiva or any of the superficial textures of the eye are diseased, you have an opportunity of discriminating the nature and seat of such disease, and of determining the qualities of its effects, by actually witnessing, not

only its precise pathological state, but of observing the product of such morbid condition. I repeat, therefore, that this circumstance gives an interest to the study of diseases of the eye, which is not generally associated with an equal attention to disease when situated in other parts.

In the treatment of acute ophthalmic inflammation it must never be forgotten that it is highly important to arrest its progress at an early stage of its existence, on account of its tendency to terminate in opaque deposition, and destroy the transparency of its pellucid textures. The same occurrence may follow inflammation of the pleura; the opposing serous surfaces of that part may be agglutinated by adhesive deposition, and may be rendered opaque, without *necessarily* occasioning any extreme injury or producing much inconvenience; but it must be remembered, that if inflammation proceed to the same extent in the eye, so that opaque deposition take place in its textures, it may render that organ useless, or, by causing it to interfere with the vision of the opposite eye, it may render it even worse than useless, although you may succeed in preventing suppuration of the globe, or any alteration of its figure; —in other words, that termination of inflammation, which in other parts is scarcely productive of the slightest inconvenience, is very generally succeeded by the total loss of vision, when it takes place in the eye. As far then as regards the preservation of the function of an organ, when the seat of disease, it is more necessary to be acquainted with the means of early distinguishing, and correctly treating, an inflamed state of the eye, than the inflammatory condition of other parts, the due performance of the function of which parts may however be absolutely essential to the preservation of life.

I need not insist upon the importance of anatomical knowledge; you are familiar with the arguments ordinarily employed to demonstrate the necessity of an intimate acquaintance with that structure, the disorder or disease of which you may be called upon to relieve or remove. However, although I have thus drawn your attention to the great importance of a due acquaintance with the anatomy of the eye, before you attempt to obtain a familiar knowledge of the pathology of that organ, I shall not occupy your time by any extended remarks respecting its anatomy; feeling assured that you are already well acquainted with this indispensible department of professional knowledge. If you are desirous of extending your knowledge of the minute anatomy of the eye, you may advantageously refer to the following works:— "Samuelis Thomæ Sœmmerring;" "Icones Oculi Humani;" "Descriptio Anatomica Oculi Humani Iconibus Illustrata," auctore Gottfrid Zinn;" "Scriptores Ophthalmalogici Minores," edidit Justus Radius.

Having, in this very cursory manner, stated my conviction that a knowledge of anatomy is a necessary preliminary acquirement to a due acquaintance with disease, and that a familiarity with the principles which regulate the treatment of disease in general is essential to a successful and scientific treatment of ophthalmic maladies, I proceed to point out the causes of that number and variety of morbid affections to which the eye is subject, and the consequent necessity for a minute and attentive investigation of the symptoms and appearances they respectively present. Many of the diseases of the eye, and generally speaking, those of chiefest importance, are very obscure in their symptoms on cursory examination, and at the same time rapidly destructive in their progress; and unless they are very promptly detected, they may arrive at that degree of establishment which no remedies will then affect. To detect, therefore, the *degree* of inflammation, as well as the *particular texture* inflamed, at our first examination, affords, in many instances, the only chance of preventing the loss of vision.

The textures of the eye are, for the most part, so totally dissimilar, that it cannot be presumed that the same morbific cause would be likely to produce an equal effect upon every part of it at one time, nor that the inflammation would assume the same appearance, produce exactly the same symptoms, and be influenced by precisely the same treatment, when it arises in different situations. We find that an agent capable of inflaming one texture of the eye has no injurious effect upon another, and we also frequently find inflammation taking place, and passing through its various stages, without at all implicating any texture in addition to that primitively affected; and if we for a moment reflect on the great variety in the situations, textures, and functions, composing the eye, we cannot be surprised that its diseases are, (I of course admit the existence of many exceptions to this general rule), as respects each other, so separate in their history, distinct in their appearance, variable in their progress, different in their termination, and peculiar in their mode of cure, and their disposition to limit their action. For these reasons I have deemed it right to describe the diseases of each texture separately, intending, however, in the course of my observations, to notice that complication of morbid affection, induced by the progression of malignant action, and also that combination of disease occu-

sioned by the extension of inflammation from contiguity, and its modification by constitutional agency.

If, after it had been explained to you that two of the humours of the eye were mere secretions, and that the third possessed so feeble a degree of vitality that its organization has been frequently questioned, and that the various textures of the eye respectively possessed in their predominant characters, the qualities of mucous, serous, fibrous, nervous, and vascular membranes in general, and also that one of them—the cornea—was so dissimilar to any other tissue of the body as to be properly designated *sui generis*,—you would feel very much surprised if I were to treat of any one or more of these dissimilar parts, under the general term of ophthalmia, limiting my description of the disease to the peculiarities of its *outward* appearance, and founding my opinion of its nature on the same circumstance; and you would no doubt feel convinced that such a mode of procedure was ill calculated to elucidate and explain the phenomena presented to our notice, by the peculiarities connected with each disease—peculiarities which it will be seen are, for the most part, consistently accounted for by a reference to the anatomical qualities of its respective parts, and the nature of their functions.

Now, in studying the pathology of the eye, in that mode in which, in my opinion, it ought to be studied, that is, by constant reference to the anatomical qualities of the part diseased, and the phenomena which attend similar morbid affections of the same texture, in other parts of the body,—you will bear in mind that whether the mucous, the serous, or the fibrous membrane of the eye, or whatever texture of that organ may be affected, there are phenomena connected with the inflammation of such texture which may be said to be common to them all; and these phenomena may be termed the general or common symptoms belonging to the particular morbid state of such texture. In this mode of studying diseases of the eye, you will free this department of our profession from much absurd and needless mystery, and effectually thwart the object of those interested individuals, who have endeavoured to give to this part of pathology a character of isolation which it does not really possess.

When, therefore, I speak of catarrhal ophthalmia, you will at once conclude that I am adverting to inflammation of the mucous membrane covering the anterior aspect of the eye-ball, and connecting it to its lids; and, when I allude to rheumatic ophthalmia, you will be aware that the strong fibrous investment of the transparent humours and delicate membranes, is the seat of the malady. In the same manner, you would infer an affection of the retina in an individual who, without any visible defect in the appearance of the eye, complained of a dimness of vision, coeval and coequal with a general diminution or impairment of the nervous power of the system. You will, in short, find the diseases of the eye at their onset limited, in many instances, to a particular texture, and exhibiting in the main the same phenomena, and passing through the same changes, as are noticed when inflammation takes place in structures of a similar nature in other situations. It is indeed important to bear these facts in mind, for otherwise you will neither be able to discriminate correctly the diseases of this delicate organ, nor adapt your treatment, with a full confidence in its propriety, to the requirements and exigencies of any case, the management of which you may be called upon to undertake.

Some of the textures of the eye intimately sympathize with the state and diseases of the constitution: for instance, the power of the retina is frequently impaired, and sometimes even totally destroyed, during lactation, and the same effect (great impairment of vision) has been known to take place as the consequence of amenorrhœa. The iris frequently becomes inflamed after the healing of a chancre, forming one of the secondary symptoms of syphilis. It is not, however, the serous covering of the iris—that portion of the membrane of the aqueous humour which is reflected upon its anterior and posterior surface—which is the primitive seat of the inflammation, but its intermediate or proper iritic structure.

Again, the sclerotica is very apt to be affected with an inflammation of a peculiar kind in rheumatic persons; it is a membrane of a dense, fibrous structure, much resembling the ligaments of joints, and those fibrous parts chiefly obnoxious to rheumatic disease; and the inflammation which we designate rheumatic opthalmia, is in fact an inflammation of the fibrous tunic of the eye, the sclerotica. It has, as will be hereafter explained, peculiar appearances and symptoms, and requires for its removal the administration of remedies adapted to the constitutional disease or tendency by which it is produced or modified; this, then, is another instance of disease of the eye, influenced or caused by the condition of the constitution, and affecting, generally, only that part of it (the eye) the structure of which corresponds with that which, in other situations, is the seat of the same malady. You will find too that it is attended with a considerable degree of pain,—a much greater degree of pain than accompanies inflammation of the conjunctiva; and this

circumstance will direct you in your inquiries after the seat of various inflammatory affections to which the eye is subject. This has been explained in various ways; but I believe it is chiefly owing, in the sclerotica at least, to the firmness of its texture, by which it is prevented from yielding to the increased and increasing size of its blood vessels, and also to their incapacity to relieve themselves, by effusion, to the same extent as distended vessels in other situations. This circumstance is well exemplified in certain morbid states of the conjunctiva; whenever that membrane becomes acutely inflamed, the softness of its texture readily permits it to yield to the distention of its vessels, whilst their plenitude is relieved, either by an increase in its natural secretion, or by purulent effusions from its surface, or by those effusions and depositions which constitute chemosis, or by the formation of pustules. Its immediate texture also admits of some deposition. The inflamed iris frequently occasions intense suffering, because it is a highly organized part, and possesses large nervous supplies, and because its natural stimulus cannot be altogether excluded;—it will be excited to a certain extent by that stimulus, which, in its healthy state, maintains the due performance of its functions. And the same reasoning will apply to the inflammation of the retina and the choroid; the one from its nervous composition, its close connexion with the brain, and its irritability to a stimulus which cannot be completely withdrawn; and the other from its high state of organization; and both from their incapacity to relieve materially the fulness of their blood-vessels by those depositions and effusions which tend to lessen their plenitude in other parts, when similarly circumstanced,—that is, when they are enlarged by the existence of inflammation. I have stated that the structure of the cornea is peculiar; it is dissimilar to any other texture, and is therefore termed *sui generis;* but there is a certain identity in its pathological conditions to those of other parts, in some of its component tissues; for instance, its external or conjunctival covering, and the cellular membrane which connects its lamellæ to each other, are liable to morbid changes, which preserve the characters of the diseased alterations those tissues undergo, when situated in other parts. You will distinguish, therefore, the *general* from the *particular* pathology of this part, and remember that the lamellar texture of the cornea alone presents those anatomical and pathological peculiarities which have caused the structure of this tunic to be termed *sui generis.*

As it is one part of my object in these preliminary remarks, to illustrate the anatomical differences in the textures of the eye, by a reference to the distinctness and the peculiarity of the diseases (considered in reference to their cause, their appearance, their progress, their termination, and their mode of cure,) with which its various parts are affected, and also their occasional limitation to that part in which the morbid process began, I may, perhaps, be allowed to refer more particularly to what was only cursorily mentioned at the commencement of these observations; namely, an affection of the retina, as a consequence of some disordered state of the constitution, and its sympathy with the condition of the uterine system.

When considering the diseases of the retina, it is important to bear in mind the predominance of its nervous over its vascular structure; it is a highly nervous part, and is, therefore, extremely liable to be influenced by those states of the system which implicate the nervous system generally.

You will sometimes find that after a patient has been much reduced by mercury, and particularly if he be under its full influence, that he will be suddenly deprived of his sight, which will probably not return until the system be cleared of that mineral, and the strength restored by tonic and invigorating treatment; you are aware also that an undigested meal will sometimes induce blindness, which may continue until the stomach be emptied of its offending contents; during lactation, dimness of vision, sometimes amounting to its total loss, will now and then occur, particularly if the individual has had several children in quick succession, and continued to suckle them for a long period. We are frequently consulted by women whose vision is nearly destroyed from this cause; they tell us they have had many children, and continued to suckle each of them until they were fourteen or fifteen months old, or even for a longer period, and that their power of vision has been gradually declining after each confinement; they will also complain of extreme debility, and great lassitude on attempting the slightest exertion. I particularly allude to this state of things, because, as will be afterwards explained, it is one of very frequent occurrence, and unfortunately one, which, in many instances, cannot be remedied; hence you will observe the necessity of paying great and immediate attention to such of your patients as may be likely to be sufferers from a cause of this nature. You cannot too urgently advise them to wean their children much earlier than is usual, and very much earlier than they will be disposed to do, unless you clearly represent to them the importance, indeed the absolute necessity, of their compliance. You cannot always control the disease at an advanced stage or season of its existence, although you may

generally arrest its progress by timely advice and judicious treatment.—"Obsta principiis" is here, therefore, as in many other cases, a maxim of the highest importance.

I purpose to treat first of the diseases of the individual textures of the eye; secondly, to speak of the various affections of the humours of the eye; thirdly, to consider the malignant diseases and other affections of the eye-ball; and lastly, to investigate the many morbid or defective states of what are usually termed the appendages of the eye.

The various operations you may be called upon to perform, will be described when treating of the diseases of those parts of the eye which render the performance of a surgical operation necessary.

ON THE LAW OF THE DIFFUSION OF GASES.

By Thos. Graham Esq. M.A. F.R.S.E.
Professor of Chemistry, Andersonian University, Glasgow*.

It is the object of this paper to establish with numerical exactness the following law of the diffusion of gases:

"The diffusion or spontaneous intermixture of two gases in contact, is effected by an interchange in position of indefinitely minute volumes of the gases, which volumes are not necessarily of equal magnitude, being, in the case of each gas, inversely proportional to the square root of the density of that gas."

These replacing volumes of the gases may be named *equivalent volumes of diffusion*, and are as follows: air, 1; hydrogen, 3.7947; carbureted hydrogen, 1.3414; water-vapour, 1.2649; nitrogen, 1.0140; oxygen, 0.9487; carbonic acid, 0.8091; chlorine, 0.6325, &c.; numbers which are inversely proportional to the square roots of the densities of these gases, being the reciprocals of the square roots of the densities, the density of air being assumed as unity.

If the two gases are separated at the outset by a screen having apertures of insensible magnitude, the interchange of "equivalent volumes of diffusion" takes place through these apertures, being effected by a force of the highest intensity; and if the gases are of unequal density, there is a consequent accumulation on the side of the heavy gas, and loss on the side of the light gas. In the case of air, for instance, on the one side of the screen, and hydrogen gas on the other, a process of exchanging 1 measure of air for 3.7947 measures of hydrogen, through the apertures, is commenced, and continues till the gases on both sides of the screen are in a state of uniform mixture. Experiments on this principle can be made with ease and precision, as will appear in the sequel, and afford an elegant demonstration of the law.

There is a singular observation of Doebereiner, which chemists seem to have neglected as wholly inexplicable, on the escape of hydrogen gas by a fissure or crack in glass-receivers, which belongs to this subject, and from which I set out in the inquiry. Having occasion, while engaged in his researches on spongy platinum, to collect large quantities of hydrogen gas, he accidentally made use of a jar which had a slight crack or fissure in it. He was surprised to find that the water of the pneumatic trough rose into this jar one and a half inches in twelve hours, and that after twenty-four hours, the height of the water was two inches two-thirds above the level of the water-trough. During the experiment neither the height of the barometer, nor the temperature of the place, had sensibly altered.

In other experiments, he substituted glass vessels of very different forms, tubes, bell-jars, flasks, all of which had fissures. In every one of these vessels, filled with hydrogen, the water rose, after some hours, to a certain height. On covering one of these vessels, containing hydrogen, by a receiver—or on filling the vessel with atmospheric air, oxygen or azote, instead of hydrogen—he never observed a change in the original volume of the gas. He thinks it probable that the phenomena is due to the capillary action of the fissure, and that the hydrogen only is attracted by the fissures, and escapes through them, on account of the extreme smallness of its atoms*.

This explanation is rendered improbable by the circumstance that hydrogen, of all the gases, was condensed and absorbed with the greatest difficulty, and in smallest quantity, by charcoal and the other porous substances, tried by Saussure. And we have no reason to

* Condensed and modified by the Author, for the Medical Gazette, from a Paper presented to the Royal Society of Edinburgh.

* Sur l'Action capillaire des fissures, &c. Annales de Chimie et de Physique, t. 24, pp. 332 334. 1823.

suppose that the particles of hydrogen are smaller than those of the other gases.

On repeating Doebereiner's experiment, and varying the circumstances, it appeared that hydrogen never escapes outwards by the fissure without a certain proportion of air returning inwards. In the experiment, however, as originally performed, it is evident, that, as soon as the water rises in the jar above its outer level, air will begin to be forced into the jar mechanically through the fissure, by the pressure of the atmosphere, independently of what we shall suppose enters by diffusion. But if we press down the jar of hydrogen to a certain depth in the water-trough, so that the level of the water without is kept constantly higher than the level of the water within the jar, then, on the contrary, a portion of the hydrogen will be forced out mechanically by the pressure to which the gas is subject. In the last circumstances, however, no air can enter by the fissure, and mix with the hydrogen, except by diffusion, or in exchange for hydrogen. Now, in a great number of experiments of this kind, the air which entered by diffusion amounted to between one-fifth and one-fourth of the hydrogen, which left the receiver at the same time. But when the circumstances were reversed, and the column of water allowed to rise in the jar above the level of the water-trough, the quantity of air which entered by diffusion was increased by a portion which entered mechanically; and varied from a third to a fourth part of the hydrogen, which escaped at the same time. The results, therefore, oscillate, as they should do, about our theoretical number. One volume air should replace 3.7947 volumes hydrogen; or the whole hydrogen, on escaping from the jar, should be replaced by little more than one-fourth of its bulk of air, and a very great contraction ensue.

But it is unnecessary to detail experiments made with the jar with the fissure, as with every precaution they were not precise, although at all times compatible with, and indeed illustrative of, the law. Thus a sensible contraction always took place in the bulk of the gaseous contents of the jar when filled with carbureted hydrogen of marshes, or with coal gas, which, like hydrogen, are lighter than air, and ought therefore to be replaced by less than equal volumes of air. With olefiant gas and carbonic oxide, which approach closely to the density of air, no contraction was perceptible, not attributable to other causes, although the gases as usual wholly escaped. In the case of carbonic acid, which is heavier than air, a slight, but positive, expansion appeared to take place, the experiment being performed over mercury.

But the same fissure or opening never allows the process of diffusion to go on with the same degree of rapidity in two successive experiments, principally, I believe, from its size changing with variations in its condition in regard to humidity. The fissures appear to be extremely minute, for we cannot cause either air or the gas employed to flow through them mechanically, at the same rate as it passes by the agency of diffusion, without the application of considerable pressure. Artificial chinks, such as that obtained by pressing together ground glass plates, or in phials fitted with accurately ground glass stoppers, allow gas to pass through under the slightest pressure, and do not answer for the experiment.

The effects were made much more striking, in some respects, by the discovery that Wedgewood stoneware tubes, such as are used in furnace experiments, admit, from their porous structure, of being substituted, instead of jars with fissures. When shut at one end, as they are sometimes made, they may be managed like other cylindrical gas receivers. Those which are unglazed are most suitable; but do not answer the purpose if either very dry or too damp, being permeable by a gas under the slightest pressure in the one case, and perfectly air-tight in the other. The following experiment illustrates the force and rapidity with which diffusion proceeds. A stoneware cylinder was entirely filled with hydrogen gas over water, and transferred to the mercurial trough; in forty minutes the mercury rose to a height of $2\frac{1}{2}$ inches in the receiver above the level of the mercury in the trough; half of the hydrogen had escaped, and had been replaced by about a third of its volume of air.

But these modes were superseded by the use of Paris plaister as the porous intermedium.

A simple instrument, which I shall call a *diffusion tube*, was constructed as follows:—A glass tube, open at both ends, was selected, half an inch in dia-

meter, and from six to fourteen inches in length. A cylinder of wood, somewhat less in diameter, was introduced into the tube, so as to occupy the whole of it, with the exception of about one-fifth of an inch at one extremity, which space was filled with a paste of Paris plaster of the usual consistence for castes. In the course of a few minutes the plaster set, and, withdrawing the wooden cylinder, the tube formed a receiver closed with an immoveable plug of stucco. The less water employed in slaking the Paris plaster, the more dense is the plug, and the more suitable for the purpose. In the wet state the plug is air tight: it was therefore dried, either by exposure to the air for a day, or by placing the instrument in a temperature of 200° F. for a few hours; and thereafter was permeable by gases, even in the most humid atmosphere, if not positively wetted. The tube was finally graduated by means of mercury, into hundredths of a cubic inch, and the notation, as is usual with gas receivers, counted from the top.

When such a diffusion tube, six inches in length, was filled with hydrogen over mercury, the diffusion, or exchange of air for hydrogen, instantly commenced through the minute pores of the stucco, and proceeded with so much force and rapidity, that within three minutes the mercury attained a height in the receiver of upwards of two inches above its level in the trough. Within twenty minutes the whole of the hydrogen had escaped.

In conducting such experiments over water, it was necessary to avoid wetting the plug. With this view, before filling the diffusion tube with hydrogen, the air was withdrawn by placing the tube upon the short limb of an empty syphon, which did not reach, but came within half an inch of the plug, and then sinking the instrument in the water trough, so that the air escaped by the syphon, with the exception of a small measure, which was noted. The diffusion tube was then filled up, either entirely, or to a certain extent, with the gas to be diffused.

The ascent of the water in the tube, when hydrogen is diffused, forms a striking experiment. In a diffusion tube fourteen inches long, the water rises six or eight inches in as many minutes. The column of water attains in a short time its maximum height, at which, however, it is never long sustained; for as in Doebereiner's experiment, air is all along entering mechanically through the porous plug in such circumstances, from the pressure of the atmosphere; and after the diffusion is over, the water subsides, in the course of several hours, to the general level. In experiments made with the purpose of determining the proportion between the gas diffused and the return air, it was therefore necessary to guard against any inequality of pressure, which was managed much more easily when the tube was standing over water than over mercury.

The capacity of a mass of stucco to absorb and condense in its pores the various gases, was made the subject of experiment, as this property might interfere with the results of diffusion. The mass was previously dried at 200° F. It absorbed at the temperature of the atmosphere, which at the time was 78°.

6·5	volumes	ammoniacal gas,
0·75	....	sulphurous acid gas,
0·5	....	cyanogen,
0·45	....	sulphureted hydrogen,
0·25	....	carbonic acid.

Oxygen, hydrogen, nitrogen, carbonic oxide, olefiant gas, coal gas, were not absorbed in a sensible proportion, even when the temperature was 58°. It is evident, therefore, that the absorbent power which stucco enjoys, as a porous substance, is inconsiderable. Placed in humid air, the same mass of stucco absorbed 1½ per cent. of hygrometric moisture. In setting, 100 parts of the stucco had retained 26 parts water uncombined, which escaped on drying at a moderate temperature, so as to avoid decomposing the hydrated sulphate of lime. It can be shewn from this, that the vacuities must have amounted to one-third of the volume of the mass.

I shall treat in succession of the escape of the different gases from a diffusion instrument into air. As the contained gas bears no proportion in quantity to the external air, the gas escapes entirely, and is wholly replaced by air. It is of the utmost importance to determine the proportion between the volume of gas diffused, and the replacing volume of air eventually found in the instrument. We thus obtain the *equivalent diffusion volume* of the gas, which it will be convenient to state in numbers, with reference to the replacing volume of air as unity. I shall begin with hydrogen

gas, although attended with peculiar difficulties, as it introduces in a distinct manner to our notice several circumstances which may slightly modify the results of diffusion.

[To be continued.]

OBSERVATIONS ON CHOLERA,

As it appeared at Castlebar, County of Mayo.

By Jonathan Osborne, M.D.

Fellow of the King and Queen's College of Physicians in Ireland, and Physician in Ordinary to Sir Patrick Dun's Hospital.

Towards the beginning of last July, in consequence of an application made on behalf of the Board of Health of Castlebar, the Central Board appointed Dr. Goodisson and myself to co-operate with them in the prevention and cure of cholera in that place, and we lost no time in proceeding thither. On our arrival, we had the pleasure of receiving a visit from the late lamented Dr. Hamilton; also from Dr. House, surgeon to the Infirmary, and from the other medical gentlemen of the town, to whose combined exertions the inhabitants are indebted far more than they can ever repay, and whose assistance received on many occasions I am happy in having this opportunity of acknowledging.

An old building, formerly a charter-school, but for many years used as a Bridewell and Lunatic Asylum, was allotted to us as a cholera hospital. On the evening after our arrival the lunatics were placed on cars and conveyed, under a guard of police, to the court-house, which was given up for their accommodation. Many of those unfortunate creatures had been in confinement for years, and, on passing through the streets, which were covered with lime, and which, with the white-washed walls, appeared as if after a shower of snow, shewed, by their words and gestures, their surprise occasioned by the extraordinary scene around them. Indeed the appearance of the town was appalling; deserted by at least three-fourths of its inhabitants, almost all the shops shut, and scarcely any but a few of the poorest classes of the inhabitants to be seen in the streets, with the glare of the hot sun and the suffocating smell of lime, or of the chloride of lime, it recalled to the recollection the descriptions of the city of the dead. The panic was universal: none remained who had the means of flying, except Messrs. St. Clair, O'Maley, and the few meritorious individuals who with him constituted the Board of Health; to whom must be added the clergy, both Protestant and Roman Catholic, who discharged their functions amidst the dead and dying with an intrepidity and zeal beyond all praise.

As it may be useful to practitioners placed in similar difficulties, I shall mention the circumstances under which we were obliged to form the arrangements of our hospital, and the means by which we rendered them effective. The building was situated near a lake, at the distance of a quarter of a mile from the town. Having been used as a Bridewell, it was surrounded with high walls, which were of great advantage to us in maintaining the discipline of the establishment. As few, if any, persons could be procured willing to risk their lives in the business, the Board of Health was compelled to send in, as nurses and other functionaries, such individuals as were forced, by the urgent necessity of obtaining a livelihood, to accept the office. Consequently, among our nurses were to be seen women of the town, and others who had been inmates of the house under its former destination; and on the first day of our opening the hospital, two of them having quarrelled, a general riot ensued, which was near being attended with serious consequences. Dr. Goodisson fortunately determined on a plan, by strictly adhering to which we not only reduced these discordant elements into order, but established the economy of the hospital on such a footing as I dare affirm has not been attained in hospitals of the longest established credit, and with servants of the highest reputation selected to attend them. The plan was this:—A table was drawn up, clearly stating the duties to be performed by each person. This was posted up in the hall. A man who had been an hospital serjeant in the East-Indies was procured, who, alternately with another, was constantly engaged in the office of superintendance. To him and his coadjutor was committed the responsibility of maintaining peace and good order, and of seeing that the directions given

with respect to medical treatment were faithfully executed. Both for these, and for all the subordinate officers, a table of fines was drawn up, which marked the penalty affixed to each offence, and the fines were entered in a book kept for that purpose, and the amount deducted from their wages. At first, some resisted, and others relied on our leniency, and believed that we would not punish them; but when they found the punishment invariably following the offence, and saw some who had been expelled for misconduct wandering about in the utmost distress, as none would suffer them to enter into their houses, they very soon submitted; and although, in some instances, during the first week the amount of fines equalled that of their wages, yet we soon had the satisfaction of seeing good order and subordination established, and the business of the hospital executed with chearfulness and regularity.

Two rooms were appropriated to the immediate reception of patients, and in each of those there were beds placed opposite the fire, with all the requisites for the application of heat, several nurses being always in attendance. A large iron vessel, filled with salt, was constantly kept on the kitchen fire, and a person was appointed to watch it, and send up the salt, at the proper temperature, in bags, according as they were called for. When a message arrived stating the occurrence of a new case, the horse was immediately put to the carriage, and in this latter were placed a mattress and a large bag of hot salt enveloped in blankets; by means of which the patient was to some extent warmed on his way to the hospital. It is worthy of remark, that one of the men employed as carriers used, of his own accord, to sit inside this closed carriage, and when the door was opened he was generally discovered in a recumbent attitude, with the patient reclining on his breast and encircled in his arms, and yet this individual never caught the disease.

As soon as the patient arrived at the hospital, he was placed in one of the beds above-mentioned, and was immediately subjected to whatever treatment was most appropriate to the exigencies of his case. As soon as the immediate danger was over and re-action established, he was removed into one of the other wards, to make room for fresh comers. In the latter wards the proportion of nurses was not much more than such as is required in a fever hospital; while, in the reception ward, the fatigue of rubbing and attending the patients was excessive, and could be endured only by frequent relays of nurses. When the disease broke out among the lunatics confined in the court-house, although they were sent into the hospital as soon as the existence of symptoms of cholera could be ascertained, yet a number of them arrived in the last stage, and others of them obstinately resisted the application of remedies, so as to increase the trouble of the nurses very much. One lunatic in the latter predicament, who fell a victim to his obstinacy, was a medical graduate of the University of Edinburgh, of the middle age, who became insane about four years ago, and was an inmate of the asylum during the greater portion of this period. We thought it due to our professional brother to attend his remains to the grave, and proceeded towards midnight, with the carriers, to the burying-ground allotted to those who died of cholera, which was most romantically situated on the side of a hill overhanging a large lake. The moon shone with uncommon brightness, and displayed more vividly the desolate scene before us, of an individual educated for a liberal profession, and who had, no doubt, entered the world with the usual buoyancy and sanguine expectations of youth, transferred from a lunatic asylum to the cold grave, with no friend or relative near him, and none but strangers and mercenaries to sympathise in his fate.

As cases of cholera are now so well known, it is needless to give any descriptions of those which were placed under our care, and I prefer to make some observations upon the individual symptoms under these heads:—1. Countenance and general appearance; 2. Sensations; 3. State of the blood and secretions; 4. Action of the muscles; 5. Pulse; 6. Temperature; and lastly, to mention the treatment adopted.

1. *Countenance.*—In incipient cases it was not altered; nor was it expressive of pain except when spasms were present. When the cold stage was established, a blueness appeared around the eyes and mouth, in the latter proceeding from the jaw at each side of the chin. As death approached, the

features sank, the eye-balls receded into the orbits, and the lips gradually passed from a purplish shade into a livid blue. The other parts of the body were unaltered, except the nails and the areolæ of the nipples, in which the gradual changes from the purple to the livid hue were generally to be observed. The same changes occurred in the interior of the mouth.

Sensations of the patient.—In at least nine cases out of ten, the disease commenced with pain and uneasiness of the stomach and bowels: when vomiting came on, it was always attended by thirst, and during the intervals the patients continually demanded cold drink, especially water. This circumstance, so unusual in other diseases, shews that the sense of nausea, which generally creates an aversion to taking any thing whatever, is extinguished by the overpowering thirst and sense of heat in the stomach. The sensation of heat was not confined to the stomach; it pervaded the limbs even when they were coldest to the touch, and the application of heat, so far from being acceptable, was (in far advanced cases especially) highly disagreeable. The susceptibilities to external impressions of touch, as well as the senses of sight, taste, and hearing, continued unimpaired. I must mention a remarkable fact, that, in the collapsed stage, repeated pinches of snuff, which were given to stimulate, produced no effect on the Schneiderian membrane. Once cholera is completely established, the actual pain suffered by the patient is very slight, being almost confined to what may arise from the cramps or from the violence of the vomiting. Three cases, however, I am able to adduce of violent pain in the spinal region, which was followed by death. The first was of a girl who had convalesced from the collapsed stage, and appeared to be advancing towards recovery, when she was suddenly seized with excruciating pain in the epigastrium and corresponding portion of the spine. After screaming violently for above an hour, she died suddenly. The second was of a child who was brought to the hospital in a state of collapse: after some hours, during which the usual symptoms occurred and the common remedies were employed, she suddenly complained of a pain in her back, and died in a few minutes. The third was of a man in Ballinrobe, who died of four hours illness under the ordinary symptoms of collapsed cholera, and, during the entire of this time, complained of nothing but an agonizing sensation in his back.

The ordinary frame of mind of the patients was not much altered. Their despondency was not greater than might be expected from the well-known fatality of the disease, neither was the cheerfulness attending recovery unreasonable, considering the danger escaped. When the coldness of the body and the vomiting continued to resist all the means usually employed, then, and not till then, did they despair of recovery; and in this state generally became refractory, and resisted the administration of remedies.

3. *State of the Blood and of the Secretions.*—In proportion to the extent and duration of the collapse which had taken place, the blood, as it issued from a vein, appeared dark-coloured and of a thickened consistence. When this blood was exposed to the air in a cup, the upper surface did not become red, or arterialized, as blood usually does, but retained its original hue, although not immersed in serum, the latter fluid, in such cases, hardly exhibiting itself in a separate form. This *non-arterialization* of the blood is particularly deserving of notice, as it proves that it has undergone some decomposition which incapacitates it from being acted on by the air, even if it were capable of being circulated through the lungs, and the function of respiration were carried on.

4. *Secretions.*—The urine was totally suppressed in every serious case. The tongue was coated with a thin but continuous coat of moist white secretion; the fluid vomited, as well as the alvine dejections, were composed of the well-known transparent liquid, containing white flakes. This fluid, when boiled, did not coagulate, although it has been described as albuminous, and a theory of the disease framed on this supposition. It appears to be mucus, and to be poured forth from the mucous surface of the intestines at the same time, and as a consequence of the same relaxation, with the profuse perspiration from the cutaneous surface. In many cases, all of them fatal, those dejections were mixed with blood, and were of an insupportable cadaverous odour. The appearance of green colour in the

fluid ejected from the stomach, was a favourable omen, and was generally succeeded by a return of all the secretions. The perspiration in both stages was almost always copious, but in the favourable cases warm and in form of a vapour; while, as collapse increased, it became cold and clammy. No remarkable increase in the bronchial tubes took place, except in one or two cases, and death was hardly ever preceded by the mucous effusion which causes what is vulgarly termed the death-rattles. At an early period of the state of collapse, the voice changed, the tone becoming sharper and at the same time weaker. This was a very general occurrence, and in many instances took place at an earlier period. Whether it was produced by a narrowing of the air-passages, in consequence of a new secretion, or by a peculiar affection of the nerves of the voice, we had no opportunity of determining.

4. *The action of the muscles.*—The action of the muscles remained perfect in the first stage and became difficult in the second, only in proportion as death was evidently approaching. Thus some of the patients walked to the hospital although very seriously affected, and most of them were able to perform all requisite muscular functions, even when the cold perspiration and the sunk features announced the fatal progress of the disease. The spasms were most frequent in the calves of the legs and toes, after these in the fingers and arms, and more rarely in the abdominal muscles. The muscular tunic of the intestinal canal also shared in the spasmodic action; as was evinced by the vomiting. This was peculiar from the violence with which the contents of the stomach were projected, in some instances to a distance of three or four feet, and with an astonishing velocity. It was unattended by any remarkable effort of the diaphragm or abdominal muscles, and appeared to be the result of contractions of the stomach and œsophagus alone. The liquid contents of the rectum were also forcibly projected in a similar manner.

5. *The pulse.*—Of all the symptoms, that which afforded the truest indication of the amount of danger was the pulse. Its frequency was of little or no importance, inasmuch as in some of the worst cases the number of pulsations was not increased above the natural standard, while in most of the collapsed cases it was considerably below it, but its strength and volume are of the utmost value as indicators of the extent to which circulation is carried on. To feel the pulse it is necessary to place the finger over the artery with the utmost gentleness, and then gradually to increase the pressure till some pulsation can be felt; without this precaution a pulse, although in existence, may be described as extinct. In the collapsed cases it is only at one certain slight degree of pressure that the pulse can be felt at all, and when the pressure is more or less it vanishes. This remark is necessary on account of the cases in which it has been stated that there was no pulse, and which yet ended in recovery. Without denying that such events have occurred, my experience leads me to the conclusion that most of the histories of recoveries under such circumstances are to be received with great caution, on account of the want of the requisite care in examination of the pulse, in consequence of which it has been incorrectly described as extinct.

6. *Temperature.*—The cooling of the body takes place with an inconceivable rapidity, a rapidity inexplicable even if life were wholly extinct, and the ordinary laws of cooling bodies were alone in operation. Thus when the collapsed state suddenly comes on, the temperature of the mouth is within the space of two hours reduced to that of the surrounding atmosphere, which could not take place even if the individual were actually killed. An experiment was performed some years since by Dr. Macartney, of the University of Dublin, which throws light upon this subject. He killed a large dog, and having placed him in an apartment to cool, found that 12 hours elapsed before the temperature of the interior was reduced to that of the surrounding atmosphere. He then took the same dog and heated him in a sand-bath up to the temperature he had when alive. He placed him as before in the same apartment, and found that he cooled down to the temperature of the surrounding atmosphere in six hours: hence it was concluded, that heat derived from the functions of life made a resistance to the cooling process twice as great as that made by heat artificially communicated.

In those cases of cholera, then, it appears that the body cools more rapidly

than can be supposed under any circumstances unless a change in the latent caloric can be taken into account. That such a change does take place is rendered probable by the copious fluid discharges derived not only from the blood but also from the more solid portions of the body; from the fat, for example, which rapidly disappears, as is seen by the sinking of the eyeballs into their orbits, and by the sudden emaciation over the whole body, produced in an incredibly short space of time.

The treatment adopted changed according to the circumstances of each case, but it was generally conformable to that assigned in the following combinations of symptoms:

First Combination.—Uneasiness and vomiting.

Essence of peppermint in effervescing draughts, with a few drops of tincture of opium; turpentine enema; fomentations of the abdomen.

Second.—Vomiting and diarrhœa, with cramps; pulse natural.

Four grains of calomel and half a grain of watery extract of opium, repeated every ten minutes till relief is obtained; leeches over the stomach or venesection according to the quality of the pulse; essence of peppermint in saline draughts.

Third.—Vomiting and diarrhœa, with cramps; fluid ejected resembling rice-water; pulse natural.

Venesection; mustard cataplasm to the region of the stomach; six grains of calomel every five minutes till relief is obtained; frictions.

Fourth.—Vomiting and diarrhœa, with cramps; fluid ejected resembling rice-water; sinking of the pulse and coldness of the extremities.

Mustard cataplasm; frictions of the extremities; six grains of calomel every five minutes. If the vomiting and sinking continue, then the mustard emetic in addition. For drink, effervescing draught with essence of peppermint or brandy, diluted largely with water.

Note.—Connected with this combination it is to be observed that when the diarrhœa continued after the vomiting had ceased, then it was uniformly checked by five grains of pulv. ipecac. c. opio repeated every hour. When vomiting continued without diarrhœa, then turpentine enemas were often successful in arresting it. In general, however, the pertinacious vomiting is the greatest practical difficulty, and one which must be overcome before we can bring our most valuable remedies into action. The great increase of vomiting produced by brandy and other powerful stimulants, is alone a sufficient objection to the employment of them. The mustard cataplasm was the most universally applicable of the remedies used, as it not only checked the vomiting but roused the whole cutaneous surface to increased action. In this combination of symptoms opium appeared to exercise no effect whatever in appeasing the stomach, and when it was retained increased the tendency to coma, which so frequently comes on after reaction has commenced. The most convenient mode of applying heat was by bags of heated salt three or four of which were in almost every case placed under the bed clothes in contact with various parts of the patient's body.

Fifth.—Cadaverous coldness; cold perspiration; sunk features; pulse extinct; vomiting and purging of congee fluid.

Mustard emetic and cataplasm; frictions; solution of carbonate of ammonia and ether; brandy; enemas of the same, in addition to the calomel powders above mentioned.

ARM AND SCAPULA TORN OFF—RECOVERY.

To the Editor of the Medical Gazette.

Sir,

If you deem the accompanying case sufficiently interesting for publication, you will oblige me by inserting it in your journal.—I am, sir,

Your obedient servant,

Jno. Braithwaite.

Macclesfield, Oct 12, 1832.

July 12, 1832.—Peter Naidin, aged 12 years, subject to epilepsy, and of a scrofulous habit, whilst working at a carding machine, fell, it is supposed in a fit, and was caught by the right arm in a revolving strap, which carried him up to the ceiling, and tore off the arm

and scapula. When seen about half an hour after the accident, he was pale and faint, but there had not been a very profuse hæmorrhage. The axillary plexus of nerves had been pulled out, and hung loose from the detached limb, to the length of two or three inches. The artery was seen pulsating at the bottom of the wound, and was plugged up by a coagulum of blood. The vein was distended, and lay upon the torn muscles like a gorged leech. The integuments presented an appearance as if divided by a sharp cutting instrument, and formed a semilunar flap from above. In attempting to pass a ligature round the vessel it slipped from the grasp, and a violent gush of blood ensued; but it was immediately seized by a tenaculum, and the hæmorrhage restrained by the application of a single strong silk thread. A ligature was also applied to the vein, and a small artery was likewise tied. The flap was carefully adjusted, and secured by two ligatures, and plaister straps and pledgets of carded cotton were laid over the whole, and retained by a broad roller, which bound down the clavicle, and prevented it putting the skin upon the stretch. A little brandy and water was given, the boy was sent home to bed, and a draught, with gtt. xxv. Tinct. Opii, was administered. No unfavourable symptoms followed, the boy only complained of slight sickness, and of soreness, as if from bruises. It would be superfluous to state the progress of the symptoms and of the treatment: it will be sufficient to add, that the wound was first dressed on the 16th instant, and a healthy purulent discharge established on the 18th. The ligatures came away on the 3d August; but a large cavity over the site of the scapula continued to discharge very freely. A seton was passed through this to excite the growth of granulations, without effect, but adhesion of the entire flap was subsequently accomplished by injecting a solution of alum, of the strength of a drachm to the half pint. The boy is now perfectly well, and suffers no inconvenience from the scapular end of the clavicle, which does not project so much as to endanger the safety of the skin.

SCIRRHOUS STRICTURE OF THE JEJUNUM.

To the Editor of the Medical Gazette.

Romsey, Sept. 22, 1832.

Sir,

I have taken the liberty of giving you an account of what appeared to me a very interesting case, and if you think it worthy of insertion in your valuable journal, you will oblige one who has been a constant reader from the commencement of its publication. It excited much interest in this town, and was believed by many people to have been a case of *real* cholera, suppressed by me through fear of alarming the public mind, and was even once reported as such to our local Board of Health, in my absence. The proof I have been able to give of the real disease of which my patient died, has therefore much calmed the general feeling on the subject.—I am, sir,

Your obedient servant,

J. N. Beddome.

Miss S., ætat. 40, a lady of deformed structure and strumous habit, came under my care about the middle of last February, complaining of various anomalous feelings of indisposition, with bilious irritation, such as she has been subject to for years, and readily yielding to a mild soothing aperient plan of treatment. The case ran on for about a fortnight in the usual way, and the only peculiarity I noticed was, that it did not so quickly yield as before, and that, under the operation of any aperient medicine, she invariably had cramp in the fingers, with the thumb drawn in upon the palm, and which she attributed to the medicine not being active enough; and true it was, that mild aperients seemed to excite this spasmodic affection, while active doses generally removed it. In about the third or fourth week she was suddenly, and without any apparent cause, attacked with violent vomiting of a green bilious fluid, attended with severe cramp and spasm, and a peculiar sunk expression of countenance, so that her family remarked to me that she appeared twice as old as she really was. This yielded in twelve hours to large bleedings by leeches, and blisters to the epigastric region, and large doses of calomel and opium, with enemata of oleum

terebinthinæ and assafœtida in gruel. The attack went off, and she was tolerably well for a few days, or a week. The first threatening symptom which then presented itself was a numbness in the fingers; next came on vomiting and cramp, and all the above formidable train of symptoms, yielding as before to the same treatment. This went on for four weeks longer, her strength sinking under the increasing severity of the attacks. I gave her internally, by the mouth and as enemata, the most powerful antispasmodics and aperients I could suggest. Externally, stimulating applications were made to the limbs, the warm bath was used, and mercurial liniment rubbed all over the liver; and when the sickness prevented her taking food, she was supported by injections of strong beef tea, with flour, and old Madeira wine, given, in the quantity of a pint, just tepid, and with a few drops of laudanum—a plan I can confidently recommend in cases of great debility. She retained them from three to four hours, with evident advantage. But at last a more violent paroxysm took place, attended with general and most painfully distressing spasm, which terminated the sufferings of my patient.

Twelve hours after death, assisted by my partner, Mr. Winter, I examined the body, when the following appearances were manifested externally:—More emaciation than I have usually, or perhaps ever seen, with great distortion of the spine and contraction of the chest. I could just span across the chest. The left lobe of the lungs adhered very much to the pleura costalis, and the right lobe particularly so. Evident marks of inflammation on the surface of the liver, and the vessels of the viscera generally tinged with blood. The gall bladder contained about forty gall stones of various sizes, a singular circumstance, as she had never complained of those symptoms which are diagnostic of that disease; but upon tracing the intestinal canal the whole mystery was solved. Three or four inches of the jejunum were in a schirrous state, firm, and as hard as cartilage, and so contracted that the little finger could scarcely be passed in. The sides of the bowel were much thickened, the muscular coat divided into membranous septa, and the internal surface ulcerated like true cancer—every vestige of the natural structure lost, and the intestine changed into a gristly substance. I should observe, that my patient never complained of pain in that particular part of the bowels where the disease was seated. The ulceration in one part had the appearance of gangrene. The examination of this case was very satisfactory—has dissipated all fear of cholera from the family, and from the town; and the conviction of the positively incurable nature of the disease has produced the full satisfaction that no remedy could have reached it.

I have sent the preparation to my friend, Mr. Ashwell, one of the obstetrical professors at Guy's Hospital, in order that it may be deposited in the museum of that noble institution, where I believe it is now to be seen.

Under the almost periodical returns of vomiting, the quantity of fluid she ejected was four times as much as had been swallowed within several hours of each returning sickness; it must therefore have been detained in the bowels above the diseased part, and ejected by an inverted peristaltic motion. The morbid appearances coincided exactly with Dr. Baillie's admirable description of schirrus of the intestine; but it was the opinion of that distinguished anatomist, that the disease seldom appeared but in the great intestines.

ANALYSES OF NINETEEN REPORTS ON CHOLERA.

Transmitted to us by the Central Board of Health.

Mr. Wagner, Public Dispensary, Chancery-Lane, (Oct. 16.)—Has not found stimulants have a constant and beneficial effect in cholera. Thinks calomel, in grain doses, every three or five minutes, with or without a little opium, has a decidedly beneficial effect. Must be continued, sometimes, till a drachm or two of calomel taken. Cold affusion, in one case, with good effect. Has seen and treated about 30 cases of the disease.

Mr. Halse, Clifton Dispensary, (Oct. 20.)—Calomel and opium. With brandy and strong stimulating liniments in collapse. Has recovered 16 cases in collapsed stage. Salines worse than useless. Cold water of no service. Of 210 cases attacked, 200 were people of

intemperate habits, and wretchedly poor. 70 of them died.

Messrs. Thompson & Son, Prince's-Road, Kennington, (Oct. 25.)—Ordinary treatment. Calomel and opium, &c. Brandy and water. Effervescing draughts. Cold blue cases hopeless and irremediable.

Mr. Lewlas, Liverpool, (Oct. 26.)—Treated about 150 cases with more than the average success. In rice-water dejections with spasms, hot treatment. Drinks of warm tea. Teaspoonful of laudanum at the instant, followed up with smaller doses of same at intervals. In cases without spasms, calomel and opium till the mouth sore. Mustard cataplasm when the vomiting obstinate: soda and cold water for common drink. In third stage, cold water as good as anything. Thinks he has seen it do good.

Mr. Miskin, Horsleydown, (Sept. 12.)—Croton oil, two-minim pill in collapse. Calomel and opium. Stimulants. Salines tried with little or no benefit.

Dr. Seeds, Kensington, (Sept. 13.)—Proposer of following plan to the Board of Health. Prompt application of heat to body by ox-bladders filled one-third with hot water: starch and opium enemas: stimulating embrocation: eascarilla and ginger infusion with Epsom salts: also soda. Tried the plan on three patients: they all "went through" the disease.

Mr. Warden, Upper Limehouse, (Sept. 14.)—Mortality 20 per cent. Chalk, rhubarb, and opium, sometimes catechu or kino added, in the rice-water stage. Lime-water and neutral salts. "After the spasm and sickness have abated, the saline treatment has been efficacious in some cases, and in others failed." Collapsed stage very hopeless, but ought to persevere with stimulants. Has tried injection of saline solution into the veins in one case, and seen it tried in two more, without the desired effect.

Mr. Holman, Burr-Street (Sept. 12).—Calomel alone, in small doses, frequently repeated. In collapse, same with warmth and gentle friction. "Has been most successful." "I have had very nearly 150 applicants in various forms of the disease, 48 of whom have died. I attribute my unsuccessful practice in the commencement of this disease to bleeding, the administration of opium, and stimulants; all of which are incompatible with the recovery of the patient."

Mr. Tachwell, Oxford (Sept. 14).—Diarrhœa cured, in many scores of patients, by small doses of Epsom salts three times a-day. A case of rice-water evacuation with cramps and prostration, "did well under the *very* frequent use of effervescing salines and soda water, with a pill composed of two grains of blue pill and rhubarb at bed-time, and clear broth in small quantities for nourishment, without bleeding, brandy, or opium, in any stage of it."

Mr. Walford, Limehouse (Sept. 16).—In rice-water stage, chalk mixture and laudanum; laudanum and catechu injections. Pills of a little mercury and rhubarb. In collapse, ordinary methods.

Mr. Casson, Holbeck (Sept. 20).—Ordinary treatment, calomel and opium, &c. Transfusion tried in collapse, with no permanent effect.

Mr. Dunlop, Baker-Street, Portman-Square (Sept. 21).—Venesection with marked advantage; saline draughts; calomel and opium; afterwards cordial tonics.

Mr. Robinson, Surgeon to the Customhouse, Cooper's-Row (Oct. 19).—From January to October, 1831, had under his care 168 cases of diarrhœa, and one of cholera. During same period of this year, 227 diarrhœa, 8 English cholera, and 48 Asiatic: of the latter, 20 died. Various treatment. Concludes that "though the disease was capable of being taken by contagion, the atmosphere was the general source of infection."

Mr. Brown, East-Smithfield (Sept. 12).—Treated 50 cases. Calomel, opium, &c. Generally successful, with perseverance.

Mr. Reynolds, Wednesbury (Sept. 18).—In collapse, stimulants with partial success. Four cases in complete collapse recovered. Oxymuriate of potass ineffectually tried.

Dr. Hawkins Villers, Newman-Street, Oxford-Street (Sept. 21).—Stimulating purgatives, &c.

Dr. Robert Stevens, Ely (Sept. 19).—Places great confidence in infusion of horseradish; calomel and opium, purgatives, &c.

Mr. Harrison, for the Preston Board of Health (Sept. 20).—Although the treatment has not been successful at Preston, yet the preventive measures have been most beneficial. By adopting the proper precautions, no recurrence of the disease in the same dwelling took place.

Dr. Blackall, Exeter (Oct. 24).—Calls attention to a remedy which "bids fair to become an important curative agent." It is milk and lime-water. To adults, two table-spoonfuls of lime-water with one of milk, cold, every ten minutes. Doses diminished for children. Remains on stomach, and allays irritability after two or three doses. If diarrhœa prevail, it is checked with opiate injections. Disapproves of the practice of indiscriminate dosing with opium, which but two often overpowers the stomach and stupifies the feelings. Rather approves of mercurial frictions; but lime-water mixture the chief remedy. In the premonitory symptoms of the nervous kind, the spir. amm. arom. was found highly beneficial.

ANALYSES & NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'Alembert.

An Introduction to Botany. By John Lindley, F.R.S. &c. &c. pp. 557.

This work, which has for some time been expected, is now in the hands of the botanical world; and while we are willing to give credit for a desire to judge fairly and impartially on the part of the two sects which at present divide it, we doubt not but that the book before us will be received with more approbation by the one party, and less by the other, than it actually deserves.

We live at the time when the restraints which hindered a free communication with the continent have been removed sufficiently long, to permit some knowledge of what was done in science, during the period of our exclusion from the neighbouring countries, to get diffused among us. Many, consequently, have become acquainted with and adopted the natural arrangement of plants, yielding to it a preference over the artificial systems formerly in use. The number of these cannot be said to be great, yet among them are some of the most eminent cultivators of botanical science now living; and the ability with which they have displayed and applied the principles of this method, has compensated for the smallness of their numbers. It may be safely affirmed, however, that the more the nature and objects of the arrangement of Jussieu are promulgated, the more numerous its disciples and advocates will become. As this is beginning to be perceived in our schools and universities, the adherents of the old systems, which they have accustomed themselves to consider as the utmost that botany could aim at accomplishing, have formed themselves into a sort of conservative party, to uphold the tottering fabric of their idolatry, and are not likely to welcome with the warmest greetings a work which, by communicating an immense quantity of knowledge respecting the structure and physiology of plants, will assist greatly in extending, as well as rendering more solid, the basis on which the natural arrangement rests.

The supporters of the natural method, on the other hand, will be apt to overrate the merits of a book, which is certain to prove so efficient an assistant to them in their endeavours to establish that system which they sincerely believe to be the best.

One cause which has greatly retarded the progress of the natural arrangement, has been the want of a good elementary work, in which its principles should be fully developed, and that accurate knowledge of the structure of plants communicated, which is essential before it can be perfectly comprehended or adopted.

Let us now see how far the present volume is fitted to supply the deficiency. It begins, as is proper, with the anatomy and physiology of plants, of which it treats separately—an arrangement of which we approve; for as the former

must always be in a more advanced state than the latter, it permits that which is certain to be easily distinguished from that which is doubtful.

Many points hitherto unsettled are here decided; but it were to be wished that the author had thrown many of the discussions upon the points remaining to be settled, either into the form of notes, or an appendix apart from the text, as their occurrence in the course of this will tend to perplex the tyro.

The physiology is treated in a very instructive way, and much that is interesting communicated. The author has certainly rendered a great service to such of his countrymen as are less acquainted with foreign languages, by introducing much of what can only be found in the most recent productions of the continental botanists.

The third book treats of the different classifications of plants; and the observations which it contains are valuable, and in most instances just. It will be admitted, that the author points out the defects of the Linnean artificial system with a very lenient touch, more so than might have been expected, or was necessary. Little is said of the present state of the natural system, as the reader is referred to another work of the same author, viz. his "Introduction to the Natural System of Botany." Many, doubtless, will think that the section on speculated modes of arrangement might have been omitted with advantage, or given as an appendix

The fourth book, which treats of glossology, or the adjective terms used in botany, needs little notice from us, farther than to observe, that not only is the arrangement good, but here, as in other parts of the book, the object is often figured on the page that contains the description—a plan which we are happy to see adopted in some of our other elementary works.

Closely connected with this is the subject of the fifth book, or phytography, and the instructions for forming herbaria, and every thing relating to collections of plants, are not only the fullest and best we know, but are followed by reflections, the truth of which we can confirm from experience.

What gives us most satisfaction, however, is the sixth book, being devoted to botanical geography, a department altogether neglected in every elementary work in the English language, yet one of great interest, both in itself, and as shewing how the distribution of plants over the earth is regulated by certain laws, deducible from the zones of latitude, the degree of altitude, and other circumstances, which, as matters capable of being calculated with precision, the inferences drawn from them will be found such as fully to entitle botany to rank as a science, its claims to which are daily becoming stronger.

The last book treats of morphology, a department likewise much overlooked in this country, but one of no small importance in relation to horticulture, and of great interest, from demonstrating the simplicity which pervades and guides all the operations of nature.

This brief survey of the contents of Mr. Lindley's work will enable us to judge how comprehensive it is; while it is but justice to say, that most of the subjects are ably treated, as well as brought fully up to the level of the science of the day, a merit possessed by no other English work on botany. Farther, the plates are well executed, and the numerous woodcuts clear and accurate.

After these statements, little commendation can be required from us. In a short time, we doubt not, it will have superseded the inferior books now in the hands of students; and it is to be wished, that medical practitioners in the country should be made aware of its existence and excellencies, and put *it* into the hands of their apprentices, that they may not have so much to unlearn, as is often the case at present.

To all desirous of becoming acquainted with botany as a science, or wishing to know what is the state of its fundamental principles, we would say—possess yourselves of this book, and you will not require any other for the elementary part of your studies. At the same time we feel called upon to remark, that it is not divested of abstract discussions quite so much as might be wished, seeing it is chiefly intended for beginners; this does not apply to the advanced student, who will find it a valuable guide to rational botany.

—

MEDICAL GAZETTE.

Saturday, November 3, 1832.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

THE MEDICAL SCHOOLS.

THE subject of education, to which we have recently directed the attention of our readers, naturally leads us to speak of the medical schools, particularly those of the metropolis, because with them we happen to be best acquainted. Since the observations in our last No. were penned, we have had an opportunity of perusing the Introductory Address, which has been published, by the Professor of Medicine at the London University, in which we find opinions on certain points connected with the subject of education analogous to those we have already expressed, but connected with various assumptions and inferences from which we are compelled to dissent.

But first we would remark, that until the legislature had vested in the Society of Apothecaries the power of requiring a certain course of studies to be pursued by all those entering into general practice, the system of professional education was extremely defective, being nearly, if not entirely, limited to the metropolis, and even there seldom extending beyond lectures on anatomy and on surgery,—or perhaps a single course on the practice of physic, if the student was ambitious of excelling the majority of his compeers. Soon after the event alluded to, however, and chiefly in consequence of the progressive demands made on the aspirants for their diploma, first by the Apothecaries, and afterwards by the College of Surgeons, corresponding improvements took place in the means of instruction afforded to the medical student, not only in London but in several of the provincial towns. Indeed, not many years ago, a mania for lecturing became epidemic, and almost every one who could get himself "recognized," forthwith set up as a—professor. If he could collect together half a dozen hearers, between pupils and amateur friends impressed into the service, he thought himself a very fortunate man, but if his numbers fell short, he went on notwithstanding; the use of his own parlour cost him nothing, and some notoriety, at all events, if but little profit, was gained by his advertisements in the daily and weekly newspapers.—This absurd state of things, however, soon cured itself, for ere long it became rather a mark of distinction not to lecture; and as many never received fees enough to cover their limited expenses, the zeal for instructing the rising generation rapidly abated. One would suppose, from the perusal of the "address" before us, that the same superficial and imperfect system of teaching still continued at every school in London—except that in Gower-street. But it is not so: the stimulus which had been given by the circumstances above mentioned was beneficially felt in those situations where all the "appliances, and means to boot," existed of affording the requisite instruction; and accordingly schools were instituted at the great hospitals; and although a compliance with the existing regulations necessarily prevents any from being perfect, yet are several of them as complete in plan and efficient in execution as any which to this hour are to be found in London; whilst others, scarcely less efficient, have sprung up in various parts of the country; in fact, wherever that most necessary appendage of a medical school existed—a receptacle for the sick, of sufficient magnitude to afford the requisite illustrations of disease.

We have endeavoured in a former

No. to shew that the system of medical education may be in various ways improved; and this idea naturally became blended with a reference to the system pursued in the schools of the metropolis, which we were wont to contemplate as all conducted on the same general plan—with some minor differences in the details, but all more or less referring to the Regulations of the College of Surgeons and Society of Apothecaries—such, we say, was our impression, when we were startled by the following passage from the pen of the learned Professor of Medicine in the London University:—"In the medical department," says he, "the superiority of the plan of the University over that, not only of Oxford and Cambridge, *but of every other school in England, is very conspicuous.*" Our first impression on perusing this sentence was, that some important feature in the plan alluded to had escaped our notice; but a little farther on we found the claim to being foremost in the race of improvement thus vindicated:—"The superiority of the plan of our University over that of all other English medical schools, consists *in the copiousness and extent of the information afforded.*" It is then stated, that courses of six months' duration on the elementary branches of medicine, are "absolutely necessary, to afford any thing like due information;" and that "courses of only three or four months' duration, and consisting of only three lectures a week, must be very superficial, and leave the hearer but a smatterer." Here, then, are the points clearly enough set forth: first, the superiority of the plan is "very conspicuous;" secondly, this superiority consists in "the copiousness and extent of the information afforded." It is impossible for us to read these statements without perceiving that the learned author is not fully aware of the state of the other medical schools, else would he not have passed upon them this general charge of inferiority, without one qualifying expression, or one redeeming exception. There are, however, two objections which may be made to the Doctor's positions—viz. first, that the "plan" is really by no means so different in the other principal schools as his exclusive language would lead the public to suppose; and, secondly, where any difference exists, it is far from being so "very conspicuous" on which side the superiority lies.

And first, with regard to the plan:—we apprehend that any one, on reading the passages we have quoted, would suppose that extended courses of lectures were not given on any branch of medicine, or at any school, except at the London University. But how stands the fact? Why, that courses, beginning the first of October, and continued to the middle or end of May, were given in some of the most important departments of medical study, before even a stone of the London University was laid!—and this from a conviction that such subjects could not be efficiently taught in a shorter period. To take surgery as an illustration, we question whether there be at this moment a single course delivered in London which is not continued from October to May. The same is done also in some instances with respect to the theory and practice of physic; and in at least three schools with respect to anatomy. Neither does it seem that the learned professor is entirely free from inaccuracy as to the actual "plan" of his own school, which he represents as consisting in "a course of lectures of six months' duration, and of almost every day in the week, on the practice of medicine, *the practice of surgery*," &c. &c. Now it happens that the surgical lectures are delivered only *three times* a week—precisely in the same manner as in every other school in the metropolis.

If the observations had applied to the regulations which define a course

as consisting of, and therefore to be efficiently comprised in, forty-five lectures, without reference to the subject, we should have fully concurred in the sentiment; or if the learned lecturer had limited himself to stating that the plan was more ably carried into effect at the school which has the advantage of his services, than at any other, we should have left it unnoticed, as a mere matter of opinion, admitting of endless discussion, but leading to no satisfactory decision; though none (and we say so most sincerely,) would be more ready than ourselves to make any reasonable concession to the school of one so entirely devoted to the furtherance of its interests, as the learned professor, some of whose opinions we feel called upon to combat. But if it be asserted that the palm belongs to the London University, because in it *all* the courses are extended, while in other schools some only are so, then we must be permitted to doubt the superiority of a system which assigns to all subjects, however unlike in nature and importance, the same period for their discussion: it requires no argument to shew that the time must either be too long for some, or not long enough for others. The extent of a course ought always to bear a due proportion to the nature of the science to be taught, and to the number of its objects. Thus in the theory and practice, both of medicine and surgery, where fundamental principles are to be established, and where each successive part, as the course unfolds itself, becomes an illustration of some general doctrine—the lectures consisting of descriptions and reasonings addressed to the judgment, rather than the memory—in such cases, we say, no doubt can be entertained of the superiority of extended courses, and here we entirely agree with the preference for them now shewn by Dr. Elliotson,—as it had previously been by others. But with respect to certain other branches, as materia medica, a great part of which is addressed to the senses, and the object of which is to familiarize the student with the appearance, and doses, and properties of drugs, by an effort of the memory rather than the reasoning faculties; then, we say, that in such case we have no hesitation in expressing our conviction that the pupil will learn more by attending a course of the ordinary length twice, than from having the subject spun out, so as to spread over six months, by the introduction of every thing that has, and much that has not, any connexion, however remote, with it—to the utter annoyance and exhaustion of both teacher and student. Never shall we forget the martyrdom of the "extended course" on materia medica, which in our time used to be inflicted in Edinburgh!

There are other subjects, with respect to which it may admit of reasonable doubt which of the two to choose,—the long course once, or the shorter one repeated. Whether, for example, will the pupil, at the end of the season, be a better anatomist, if the teacher give but one series of lectures throughout the season, entering elaborately into all those minute discussions which are requisite to fill up the time; or if he make the second division of the session so far a repetition of the first, that the natural anatomy of the body is gone over twice? We say "so far," because we know that it is usual, for the sake of variety, to introduce physiology into the first, and pathology into the second course. We are aware that a difference of opinion exists in this respect, some metropolitan lecturers preferring the former, and others the latter plan: we are also aware that the subject has been discussed by several lecturers, and among others that Mr. Stanley, (who is probably the most experienced anatomical teacher now in London), as well as others whom we could name, after due deliberation, decided in favour of the

shorter courses, as more to the advantage of the pupils.

But to return. Two other points are alluded to as illustrating the superiority of the plan at the London University; namely, the illustration of the lectures by preparations, plates, models, experiments, &c.; and secondly, the instituting of examinations. We need scarcely inform our readers that neither of these are peculiar to any school: the museums at all the great hospitals sufficiently shew the attention that is paid to the materials of illustration, for obtaining which, indeed, their circumstances give them excellent opportunities. As to the other part of the plan—that, namely, of having occasional examinations—it is adopted at many, if not at all, the schools; while in some instances it has been carried to an excessive, and therefore injurious extent, constituting a mere system of *grinding*.

From what we have said it will be gathered, that, in our opinion, the learned lecturer, in advocating the cause which it is very natural and very proper that he should support, not only has lost sight of the rival institution, against which the closeness of its imitation was made matter of taunt in a previous introductory delivered from the same chair; but he also seems to have forgotten the many eminent men who are at this moment employed in teaching the various branches of medicine in the metropolis, on plans so similar to that adopted at the London University as to render it obvious that the atmosphere of Gower-street must be exceedingly favourable to the growth of intellect, if the pupil there be filled with knowledge even to overflowing, by the same method which elsewhere "leaves the hearer but a smatterer."

To some it is possible that the silence, under an implied charge of inferiority, of those whose cause we have endeavoured to advocate, may appear as a tacit admission that the imputation is deserved: but of course the learned author of the address before us cannot be among that number, — to him the diffidence which ever attaches to merit must be familiar; and no doubt he can well appreciate the reluctance with which those who are devoted to the pursuits of science obtrude themselves and their pretensions on the notice of the public.

P.S. Since the above was written, we have learnt that one of the lecturers (Mr. B. Cooper, at Guy's) who last year gave an "extended" course on anatomy, has this season gone back to the old plan — *at the request of his pupils.*

HIGH-EARED RACE OF MEN.

M. Dureau de Lamalle has made out the strongest evidence in proof of the existence of a distinct variety of the human race, characterized by the position of their ears. Not only, as they are represented in the Memnonium, and other Egyptian statues and coins, were the old Egypto-Caucasians remarkable for their high ears, but in more than forty mummies which were unrolled and examined by M. de Lamalle, at Turin, the auricular foramen, which, drawing a horizontal line, is placed in us on a level with the inferior part of the nose, was in these examples found to be on a level with the middle of the eye. The elevation, as measured, amounted to a full inch and a half. The facial angle was at the same time found equal to that of Europeans, but the temporal region much more depressed than in our variety.

Nor does it appear that the high-eared race is extinct: there are instances of it among the people of Upper Egypt at this day; and indeed there is in Paris at present a teacher of Arabic, a Copt of Upper Egypt, who is possessed of this conformation in a most decided degree.

MANCHESTER MEDICAL SCHOOL.

We have been much gratified by the report sent us of the public dinner given last week in Manchester, to commemorate the opening of the New Theatre in Pine-Street. The following particulars will, we think, be found generally interesting. Benj. Braidley, Esq. the Boroughreeve, filled the chair. On the health of Mr. Turner, the founder of the theatre, being drunk, that gentleman returned thanks. He claimed for Manchester the merit of having largely contributed to the diffusion of useful knowledge. That town had long held, and continued to hold, a high rank for its support of literary and scientific institutions. The Literary and Philosophical Society, the Natural History Society, the Royal Institution, and the Botanical and Horticultural Society, were so many proofs of the interest taken by the inhabitants in the cause of science. But it should not be supposed that the cultivators of medical and surgical knowledge had slumbered all this time, because they had worked on in comparative seclusion. He then pronounced an eulogium on the memory of Percival, White, Gibson, Simmons, and other eminent professional men of Manchester. He would not claim to himself any exclusive merit in establishing the school: when he entered on the duties of a lecturer in that place, it only required an organization of plans, and the bringing lecturers together; and he was most willing to share with others, particularly White, Gibson, Ransome, and Jordan, the palm for such a service. On the health of the other lecturers of the Pine-Street School being drunk, Dr. J. L. Bardsley acknowledged the toast in an elegant speech, in which he took occasion to pay due tribute to the other schools of Manchester, and concluded by proposing the health of the lecturers at those schools. Mr. Jordan, returned thanks, and observed, that fourteen other towns had followed the example of Manchester. Dr. Bardsley, in acknowledging the toast of the "Manchester Royal Infirmary," said, he was well aware that Manchester was justly proud of its eminence in manufactures and commerce; but he rejoiced that the inhabitants had still more reason to be proud from another source. The Royal Infirmary might be compared to a tree planted in a good soil; it had taken deep root, and by diligent and successful cultivation had risen to its present gigantic height, dispensing its healing balm in every year to 19,000 of our suffering fellow creatures.

Dr. Dalton returned thanks for the Literary and Philosophical Society; and several speeches were afterwards made, among others, by Dr. Holme, Mr. J. E. Taylor, Mr. Radford, Dr. Alexander, Mr. Wilson, and Mr. Gordon. Before the conclusion of the convivialities, Mr. Turner took occasion to announce, that the senior pupils in the old school who had obtained medals were Mr. Golland and Mr. Ker; and in the new school, Mr. John Kinder Wood.

COLLEGIUM WAKLEYANUM.

To the Editor of the Medical Gazette.

Sir,

I have been strongly solicited to offer myself a candidate to the London College of Medicine, but have declined doing so until I have obtained some information on the subject from those competent to give it. This College is said to have been instituted in 1831. Pray, by whom was it instituted, and what are its legal constitution and privileges? Has it really a power of granting the degree of doctor in medicine? and would the title of doctor of the London College of Medicine be recognised by the courts of law? Will a degree from this College enable a person to practise medicine without fear of interruption from the Colleges of Physicians and Surgeons, and the Apothecaries' Company? Or is the whole concern a mere humbug—an association of a few individuals *calling themselves* a College? because, in that case, I should still decline joining them, not choosing to undergo the ridicule of all my acquaintance, and to become the laughing-stock of the public at large.

Cautus.

October 20, 1832.

[Cautus is a prudent man; but he ought to know that we laid even the ghost of Wakley's College long since. Who are the jugglers that would pretend to raise it again?—Ed. Gaz.]

DUTY ON SKELETONS, MODELS, ETC.

THE following letter explains itself: we give it insertion for the benefit of those whom it may concern.

Treasury Chambers, Oct 30, 1882.

SIR,

Having laid before the Lords Commissioners of his Majesty's Treasury your letter of the 15th instant, addressed to Viscount Melbourne, on the subject of the inconveniences to which anatomists are subjected, by the operations of the bill for regulating the Schools of Anatomy, and requesting his Lordship's interference, in obtaining relief from the duties at present payable on the importation of articulated skeletons, wax models, and other preparations illustrative of the anatomy of the human body; I am commanded by their Lordships to acquaint you, that the practice which has been adopted with regard to the admission of anatomical preparations, models, &c. has been to remit the duties on such articles when imported expressly for the use of any particular school, or to be deposited in any public museum, or when brought to this country by foreigners, for the purpose of lecturing thereon, or the advancement of anatomical science: and my Lords will not object to extend these regulations to the admission of human skeletons; but they would not feel justified in sanctioning the remission of duty generally on such articles, when imported for sale. Individual applications must, therefore, be made to this Board, in such cases as may come within the above-mentioned regulations.

I am, sir,
Your obedient servant,
SPRING RICE.

Dr. Somerville, 5, Saville-Row.

HOTEL DIEU, PARIS.

THE MODERN ABELARD; WITH CLINICAL REMARKS ON MUTILATION OF THE GENITAL ORGANS.

By M. DUPUYTREN.

AFTER some remarks on mutilation of the genital organs caused by machinery, M. Dupuytren observed that it was not unusual in quarrels for the vanquished party to seize the victor by the genitals: he saw a case in which a large portion of the scrotum was torn off with the teeth; and he met with another case still more remarkable, in which both testicles were dragged away by the hand of a furious adversary. People in a state of delirium often mutilate themselves in this way; and weak-minded persons sometimes cut off their testicles for the strangest reasons. The professor knew one man who did it through vexation at the ill conduct of his daughter: another, who was displeased with his wife, proceeded to cut off his penis, but he was stopped before he had got farther than through the urethra and one of the corpora cavernosa—about half through the organ. He was brought to the hospital, a sound was introduced into the urethra, and reunion was effected: but the consequences were singular. In its flaccid state the penis did its duty very well, in allowing the urine to pass; but when erection took place, the cicatrice preventing it in one of the corpora, it was confined to the other: hence there was a most extraordinary drag and curvature in the penis, and a deformity, said the professor, truly hideous to behold.

These remarks of M. Dupuytren arose out of a case of a most shocking nature now under his care—a case, in fact, the counterpart of the horrible atrocity committed on Abelard. It is as follows:—

Removal of the right Testicle; Cure.—Removal of the left, eight weeks after, by violence—Horse-practice for the suppression of the Hæmorrhage.

Constantine M. 24 years of age, an operative in a foundry, applied at the Hotel Dieu, on the 14th of October, about two in the afternoon, for relief in the suppression of a scrotal hemorrhage. The left side of the scrotum was swelled to the size of two fists, and violet coloured. It bore a longitudinal incision, between the lips of which there was seen a large bloody clot, and across this clot a continual oozing of fluid red blood. M. Dupuytren removed with his finger about a pound weight of clotted blood, and perceived that the oozing came from the cellular tissue, which was like an overcharged sponge. He then, with a pair of scissars, removed the infiltrated part of the cellular tissue. Three little arteries made their appearance, and were tied: the hemorrhage then ceased.

In the course of this treatment it was found that the testicle was not present: but the extremity of the spermatic cord was seen engaged between two little pieces of wood, eighteen lines in length, each of them demicylindrical, but by their apposition forming a cylinder of a couple of lines in diameter, and confined in that shape by a strong ligature of packthread: in short, it was a regular *clamp*, such as sow-gelders use for splaying domestic animals. Extra-

ordinary as all this was, the wonder was increased when on examining the right side of the scrotum there was found a perfect cicatrix, but the testicle was wanting.

The patient gave the most contradictory accounts of himself; but from a careful investigation of circumstances, the following seems to be a true account of his misfortune:—

He had cohabited with a married woman, whose husband, having come upon him by surprise, deprived him of his right testicle as a fitting punishment. This was about six or eight weeks ago. But the unfortunate lover was no sooner well than he returned to his old habits: it was after having spent the night with his paramour that the husband caught him a second time, and, with the assistance of two stout men whom he brought with him, tied the patient's hands behind him, fettered his legs and fastened them to a bed-post, when one of the ruffians knelt on his chest and stopped his mouth, while the others were performing the emasculation.

Notwithstanding this horrible treatment, the patient persists in concealing the names of his butchers: some of the circumstances, however, attending the case, may lead to their discovery. The wound was evidently inflicted by a practised hand; the incision was neither too large nor too small; and the precautions taken against hæmorrhage by the veterinary expedient mentioned above, yet without the skill to provide against the bleeding of the small arteries, shew with much probability that the operator must have been some sow-gelder or veterinarian by profession.

The clamp (*tasseau*) was removed, and a ligature placed instead; which has since come away. The patient is going on very well; he is, indeed, in no danger; "but his doom is sealed—he is erased for ever from the list of men—he is incompetent for the duty of reproduction!" The Professor gave particular directions that the poor fellow should be kept quiet—that his *moral* should be tranquillized as much as possible after such an agitating calamity.

There is also another case of mutilation in the hospital at this moment, and perhaps one not less remarkable in its history than the preceding. The person is 45 years of age, with black beard and mustachios. He came in for fever; but his scrotum, testicles, penis—all his genital apparatus, are clean off. There is just one median cicatrice, deep enough to present the appearance of *labia externa*. A little nipple-like projection, with a perforation in it which would seemingly admit about the head of a pin, marks the place of the urethra. No consistent account could be got from this individual how his misfortune happened. At first he said it was from a kick of a cow; but he has since confessed that he did the deed himself, with a view to suicide, after having suffered a severe pecuniary loss. He had heard, he said, of a physician who put an end to himself by this sort of mutilation, and he wished to follow his example. The hæmorrhage he described as having been very great, but it was ultimately suppressed by the copious use of cold water.

GUY'S HOSPITAL.

Case of Congenital Malformation of the Heart.

[Communicated by Mr. Dade.]

William Hodgson, æt. 16, rather a robust youth, had, since his birth, been much troubled with palpitation of the heart and great dyspnœa upon the slightest exertion. He had also suffered much from frequent attacks of pain in the left side. He was admitted into Guy's Hospital on the 28th of March, 1832, under the care of Mr. Key, for an indolent ulcer on the left leg (depending upon feeble circulation), which, as well as the right, was rather œdematous. He was also, a short time after his admission, affected with purpura. There was nothing particular in the appearance of the countenance beyond the usual characteristics of heart disease—viz. anxiety of countenance and lividity of the lips; and it was only upon increased exertion that his face became decidedly blue. Pulse was regular, but slow and feeble. It appears he left the hospital of his own accord, April 22d. From this time up to October 3d no particular aggravation of the disease occurred, until he was attacked with fever, when he was re-admitted on the latter date, under the care of Dr. Addison. During this time (but never before) hæmoptysis supervened to a great extent frequently, and on the 13th he died. I have not thought it necessary to lengthen the case by detailing the remedies administered; from which nothing but a palliative effect could be expected. The stethoscopic indications were as follows:—

Action of the heart very tumultuous. Upon placing the hand upon the anterior part of the chest a peculiar vibration was communicated to it. Contraction of the right ventricle louder than usual, and accompanied by the "bruit de soufflet;" action of the left much embarrassed, feeble in its contraction, and emitted a peculiar flapping noise. Dr. Addison and Mr. Key considered it a case of imperfect septum ventriculosum. The correctness of their diagnosis was verified by the postmortem appearances. The inspection took place forty-eight hours after death; morbid alterations as follows:—

Thorax.—Old cellular adhesions between pulmonalis and costalis of the left side.

Right lung not adherent; the cavity contained a small quantity of bloody serum; substance of the lung rather œdematous, and interspersed with miliary tubercles.

Left lung enormously engorged with blood, and easily broke down under slight pressure. At the apex of the superior lobe there was a tubercolous excavation containing small particles of earthy matter. The rest of the lung presented the same morbid appearances as the right. Mucous membrane of the bronchiæ highly vascular and turgescent. Pericardium contained about ℥iij. of sanguinolent serum. Heart rather enlarged. Right auricle dilated. Foramen ovale perfectly closed. Right ventricle, from being hypertrophied and dilated, presented the same appearance as the natural size of the left. Tricuspid valves healthy. Pulmonary artery about half its usual size at its commencement; sigmoid valves corrugated and thickened. Left auricle and ventricle collapsed; parietes much attenuated, and the cavities diminished. Mitral valves healthy. The aorta arose from the right ventricle, below and rather to the right of the pulmonary artery, and anterior and inferior to the aorta was the opening in the septum, about the size of a shilling; the superior part of its concavity being bounded by the commencement of the aorta, the inferior by the remaining of the septum. Aortic valves healthy.

Abdomen.—Liver healthy. Lower portion of the ilium free from ulcerations, but presented patches of enlarged glandulæ aggregatæ.

NOTE FROM MR. MACLURE.

Mr. Maclure has written to say that we have not represented his opinions correctly in our analysis of his Report on Cholera: we subjoin the passage alluded to *in his own words*, and any one who feels sufficient interest in it may judge for himself whether we did or did not render it fairly, at p. 115 of our last No.

"Though the undersigned has treated, since the commencement of this year, many cases of cholera, and still more of diarrhœa, he does not think that any of the cases which came under his notice were new to this country and climate; certainly none of them were so severe as some which he met with in the summer and autumn of 1831, before the present epidemic was supposed to have reached Great Britain. Of course he cannot be sure but that some of the cases which he has treated this year might have ended in the malignant cholera, if they had been neglected or improperly treated at the commencement."

WEEKLY ACCOUNT OF BURIALS,

From the Bills of Mortality, *Oct.* 30, 1832.

Abscess	3	Fever, Typhus	4
Age and Debility	30	Hæmorrhage	2

LECTURES

ON THE

THEORY AND PRACTICE OF MEDICINE;

Delivered at the London University,

BY DR. ELLIOTSON.

CUTANEOUS DISEASES.

Erysipelas—Treatment: concluded.

IN speaking, gentlemen, of erysipelas the other day, I merely laid down the general principles of treatment—those measures which are of a decidedly antiphlogistic kind, and those which are necessary when the body requires supporting, or even stimulating.

Bark.—I mentioned that you cannot lay down the treatment in any universal way; that you now and then must bleed: in other cases you must give nourishment of the best description—wine and bark. But I did not mention that some old practitioners imagine, from having learned it in their youth, that bark is a specific for this disease; and in every case of erysipelas they give, or (as they call it) "throw in" the bark. It was at St. Thomas's Hospital that this practice was first established. Dr. Fordyce gave bark in erysipelas with very great success, and his colleagues and successors, down to within a very few years, all adopted the same practice, and extolled it highly. Now I never fell into the practice of giving bark universally, whatever was the state of the patient. Very often there is tenderness of the epigastrium; very often there is vomiting; very often there is a robust constitution and a strong pulse; in short, a decidedly inflammatory state; and I could not in my conscience think of treating the case with bark. No doubt bark might be given in many inflammatory diseases without doing any harm, except so far as it prevented you from doing good; but you see many cases where antiphlogistic measures are decidedly required, and I could not bring myself to omit them. There are many gentlemen now in practice who were educated under Dr. Fordyce (for he was the principal medical lecturer in London at that time), and who regularly give bark in this disease. I have no doubt that a number of their patients get well, because many cases are assisted by the bark, and many cases will get well of themselves, if you do not adopt any measures which do serious harm.

There is certainly a great peculiarity in erysipelas: you will frequently see cases do well with little or no treatment—without those evacuations that other inflammatory diseases require. I have seen cases neglected, which, had they been pleuritis or enteritis, would have proved fatal without vigorous antiphlogistic treatment; but which, notwithstanding they were neglected, did exceedingly well.

Specific Character.—Erysipelas is considered a specific inflammation; not contagious like small-pox—not limited to its occurrence once during life—but still altogether of a peculiar nature. It will bear stimulants, and bark, and nourishment, in a way that other inflammations will not; nor will they do the same degree of harm that would ensue from their exhibition in other inflammatory complaints. You may omit antiphlogistic measures to an extent that you dare not in other cases; and it will require on the whole, however violent the inflammation, much more moderate evacuations, and less bear great evacuations, than other inflammations. There is another important consideration: when you are in doubt as to whether you should support these patients or not—whether you should not give them wine, bark, quinine, and porter in moderation—you may then do it with the greatest safety. I never saw

harm done when it was near the balance. In other cases of inflammation, I have thought that the time was arrived for this species of treatment when it was not, and I have been obliged to desist; but in erysipelas such a circumstance very seldom occurs. As to sulphate of quinine, that may be given in most cases of the disease, and I never saw injury arise from it under any circumstances. I have seen decidedly active cases of this disease treated with quinine, without their being the worse for it: I do not know that they were improved, but certainly they were not rendered worse. Dr. Heberden gave it as his opinion that bark would not do harm in inflammation; and in a great many cases it is true; but as to quinine, I have given it over and over again in inflammation, for some other reason—for example, in ague, where I have not seen the inflammation increased; but in these cases I have always treated the inflammation, at the same time, by proper measures. Hence, in erysipelas, if you feel disposed to give quinine you always may, except there be vomiting; and even where there has been vomiting I have given it, and it has put a stop to it. Therefore, though this is a disease that is to be treated by decided antiphlogistic measures, yet it permits the exhibition of wine, bark, and porter; and though you adopt antiphlogistic measures, yet it does not bear those evacuations that other inflammatory diseases do. It sooner requires supporting measures, and a larger number of cases require support, than perhaps in any other inflammation.

Starch, Zinc, &c.—Respecting local applications, I mentioned merely heat and cold. I have found cold answer better than heat. Some practitioners sprinkle starch and other powders over the skin; and I do not know that it does any harm, provided the powder be of the slightest possible description, so as not to lie heavy on the part. If there be vesication, it certainly is a good plan to sprinkle a little powder, for the purpose of absorbing the discharge which may have occurred. The oxide of zinc, or calamine powder, either the one or the other, is as good an application as you can employ; but this should not prevent you from applying cold water, which you may still do by means of cloths.

SQUAMÆ.

I now proceed to consider those inflammations which, although they are attended by no secretion under the skin, still cause such a disease of the cuticle that a scale is produced. In those inflammations which I have already spoken of—lichen, strophulus, measles, and so forth—there is for the most part a degree of scurfy exfoliation after them; the cuticle is separated more or less, either in fine grains, so as to form a scurf, or in large portions. But the diseases we are about to consider produce something more than a separation of the cuticle, which becomes a little diseased, and lies in plates upon the inflamed spot. That is the only difference. These thickened portions of cuticle are called scales. The definition of Dr. Willan is, "a lamina of morbid cuticle, hard, thickened, whitish, and opaque." A scurf is only a little exfoliation of cuticle, the cutis not becoming diseased; but if the cuticle be not merely separated, but become hard, thickened, whitish, and opaque, then it is called a scale. Still, however, there is no ulceration; there is neither pus nor serum, nor any thing else effused under the cuticle; but the cuticle is separated, and not only separated as in common inflammation, but thickened and diseased. Now in this order of diseases there are three genera, and these are of common occurrence; diseases that you will have to treat every day—diseases of a chronic character. None of them are contagious; they may occur twenty times during life, and they are all disposed to become chronic.

Pityriasis.

Species.—The first of these of which I will speak, is Pityriasis. I speak of it first, because the scales are exceedingly thin, and the affection altogether very superficial. When it occurs in the head of children, it is called *P. capitis*, dandriff of the head. When a child's head has this disease, a fine powder falls off in all directions; in fact, it is called pityriasis, from its resemblance to bran. It is a very common disease of children. Now and then the inflammation is considerable under these scales, and then it is called *P. rubra*. It is only worth while for you to remember, that just according to the degree of inflammation of the skin underneath the scale, the part is either rather pale or pretty red.

Duration.—This is a disease which lasts only for a time in children; for the most part it gets well, and I dare say sometimes spontaneously.

Treatment.—It is best treated as inflammation, having the parts pretty well moistened twice a day, keeping them exceedingly clean, and cutting the child off from stimulants. Small doses of hydrarg. c. creta, I believe, are the best internal means that can be used—the best, at least, that I have found. It is said by Bateman to be removed by antimonials, with the decoction of woods, but I have no faith in these; and I know, that what I have stated, answers better than any thing else. You may keep the parts soft by ung. zinci,

which is one of the best; but it is well that you should know, that in diseases of the skin, ointment, however mild, may produce irritation. I have seen many diseases of the skin kept up by medicinal applications. It is well to remember this, because you might imagine that it was only something stimulating in the ointment that was injurious, and that a milder ointment would answer better; whereas, it is the ointment *itself* which produces the mischief. I have seen the disease entirely kept up by patients putting on grease, and when they have exchanged it for calamine powder, and kept the parts moist by rags laid on them, they have improved almost immediately.

Pityriasis is said to occur frequently in another form, called *P. versicolor*;—I am not sure that it is really the same disease. You will see it in young women, particularly about the breast; and sometimes on the neck there are yellow patches of it. Now this state is called by Willan P. versicolor—variegated pityriasis; but Rayer does not place the disease under pityriasis. Now and then there is a little redness, a little heat, and a little scurf.

Treatment.—I do not believe that this is under the influence of internal medicine; at least, I have tried a great many prescriptions without any effect; but you may destroy it with acids. The thing is painful; but you may have a part painted, and if that be cured, and the patient has no objection, you may go all over it. It is a complaint that is not attended by derangement of the constitution any more than the scurf of children. I do not know why these affections occur; the causes are not known that I am aware. It may now and then arise in children from weakness, and it may be right to give tonics, some preparation of iron or quinine, and good nourishment; but, for the most part, I believe the treatment I have mentioned, hydrarg. c. creta, and mild diet, answer very well.

Lepra.

The two others in this class you will see every day. They are diseases which a great number of young men and women are particularly subject to; and I think they are more common in the latter than in the former. These two affections are very similar to each other; they run into each other, and, indeed, I think they might be considered as the same disease in different forms.

The first of these is called *lepra*. Lepra does not signify leprosy, according to the ancient term; it is a different affection. This is by no means a loathsome disease; it consists merely of red spots on the skin, or patches covered with scales. For the most part it does not affect the health, except so far as it may sometimes be connected with an inflammatory state; otherwise it is merely disfiguring and inconvenient.

Character.—In the disease denominated lepra, to distinguish it from psoriasis, you will find that the patches are circular—that the margin extends a little beyond the skin, and is red and elevated. The cuticle is sometimes very much thickened, and sometimes very white and silvery. You will first see the disease in dots, varying in size from a pin's head to a pea, and these become confluent and form patches. It is about the outer part of the elbow, and below the knee, that these are most conspicuous. You will see it too about the occiput, behind the ears, and it will affect the face more or less, and the whole of the scalp. Of course the character of the disease is shewn more in one part than in another; and it is a good general rule when you investigate cutaneous diseases, not to be satisfied with looking at one part of the body, for the disease may be but ill characterized at one part, and extremely well characterized at another. It is best, in looking at cutaneous diseases, to examine all over the body; and in doing so, you will come to one part where the disease is so characteristic, that you may name it without any difficulty. The patches in lepra are sometimes as large as a crown piece, and the disease much more frequently affects the extremities than the trunk, but you see it also very much about the head.

Species.—The most common form of the disease is that which is called *L. vulgaris*. You will observe [exhibiting a plate] that the eruptions all affect a circular form; that the large patches, which are made up of an aggregation of small ones, are still more or less circular, and you will observe also a red margin around them, which is elevated. When they heal, they generally do so from the centre. If we had a hospital attached to the school, I could bring patients before you in order to illustrate these various cutaneous diseases. This is the most common form, but I mentioned that now and then the scales are very silvery; they are really as silvery as the scales of a fish, and then it is called *L. alphoides*. Now and then the scales are a little dark, and then it is termed *L. nigricans*. You may remember that sometimes it is very white, and sometimes it is black; that will do as well as remembering vulgaris, alphoides, and nigricans. It is a great mercy that we have no other names given for the intermediate shades.

Age at which it occurs.—This is a disease which I do not think I ever saw in an in-

fant, or in a child. You seldom see the disease in patients under 10 or 11 years of age, and even then it is not so frequent as in the first stage of adult life. From about 17 or 18, up to 30, you see the disease more commonly than at any other period. Why this is I cannot tell, and as to the cause, it is very common to discover none; but now and then one is able to trace it to a person having drank cold water, or some other cold fluid, when overheated. This is a common cause of lepra and a variety of diseases of the skin which are not contagious.

Duration.—It is a disease which will last a very considerable time, perhaps two or three years, though sometimes it will go off in a few months. It is an affection which will recur, and now and then there is very great tingling and very great heat of the skin. I always make it a rule to inquire in this, as in other chronic diseases of the skin, whether there are not some internal symptoms; and in a large majority of cases you will hear the patient complain of drowsiness, headache, heat of the head, and giddiness; and if you take away blood you find it buffed, and perhaps cupped. This is an every day occurrence, and it is by no means dwelt upon by Willan and Bateman as it should be; in fact, they were only forerunners to better writers on the subject; they were occupied as historians, pointing out diseases, rather than pointing out the pathology or the rational mode of treatment. But if you will make inquiry in cases of lepra, as well as in other diseases of the skin, you will find the head affected at first, and frequently throughout the course of the disease. There are cases where nothing can be discovered about the head, but even there you find the irritation and tingling very much relieved by bleeding.

Psoriasis.

The other disease which bears so great an affinity to lepra, and runs into it, is called *psoriasis*. The difference between the two is, that in psoriasis the patches, or spots, are not circular, but more or less oblong; the margin is not raised, and it more frequently heals from the margin than at the centre.

Character.—In this disease the skin is very apt to crack; you see fissures in the skin, called *rhagades*, and there is for the most part much more inflammation than in lepra. You may, in a great number of cases, easily distinguish between these affections. In lepra the patches are circular, the margin is elevated, and there are no cracks; whereas, in decided psoriasis the spots are oblong, the margin is not elevated, and there are fissures or cracks. But in intermediate cases you might almost defy any one to state positively whether it is lepra or psoriasis; they certainly run into each other. There is very frequently great irritation in this particular form of the disease; it tingles and smarts severely.

Species.—You will observe the different species from the plates. In one you observe a form where there is little inflammation, and it occurs in dots—it is called *P. guttata*; if it occur in patches, it is called *P. diffusa*. If any cause of irritation be applied to the skin, this may be aggravated; for instance, in washerwomen the soap may produce this effect. Now and then it takes place very locally in the palms of the hands, or the soles of the feet—but chiefly in the palms of the hands, and it is called *P. palmaria*; there are generally cracks in this variety. The patches, you perceive, [exhibiting a plate] are oblong, and the margins not raised. There are rhagades and fissures, which are so common that you rarely see the disease without them. This affection will sometimes last for a great length of time, and cover the whole body; the cuticle is separated in great quantities, and beneath it there is more or less fluid oozing forth. The more severe the inflammation, the greater is the disposition to crack. Now and then this disease appears in a form like that of worms, and then it is called *P. gyrata*. This woman [exhibiting a plate] is ornamented very beautifully. I never saw this form of the complaint; it looks as if her mother had longed for snakes.

You have only, then, to discover whether the disease is attended by scales, and if it be, it is one of the three species to which I have now adverted. If it be pityriasis, you find the scales very minute, coming as near to scurf as possible; if the scales be thick, the patches circular, the margin elevated, and there be no cracks, you may depend upon it it is lepra; if, however, the patches assume an oblong form, and there be cracks, it is psoriasis.

I stated that these diseases are not contagious, and that is allowed to be the case; but two or three times I have met with the disease apparently from communication with another person labouring under it. It has happened to me, I am quite sure twice, if not three times, to see persons have lepra come on after using the towel of, or sleeping with a person affected with, the complaint. These instances occurred in St. Thomas's Hospital; one about three years ago, and two, I think, within the last twelvemonths. It might have been chance; it is impossible for me to say it was not chance; but it so happened that another person had lepra about a week or a fortnight after employing a towel which had been used by a person with the affection; and in another case, a young woman slept with another who laboured under it, and she had patches as large as a half-crown.

I cannot venture to say that the disease is not contagious.

You will see one form of the disease which you might consider a pustular affection; namely, *P. inveterata*. Psoriasis sometimes lasts a great length of time; in fact, till the whole body is covered with scales, so that scarcely an inch is free from it. The disease being very severe, those cracks which are peculiar to it, or characteristic of it, become very considerable, very large, and they produce a degree of oozing. The irritation of the skin is sometimes so great that it not merely produces a diseased enticle, but perhaps an oozing of fluid under the enticle, so that psoriasis runs into lepra on the one hand, and into tho e diseases which are characterized by a morbid secretion on the other; but still the cracks and the occurrence of a scaly enticle shew that it is a scaly disease. But you must look at these things as pathologists, and not as historians.

Treatment.—In the treatment of this disease, it is improper to begin with any empirical medicine till you have ascertained whether there is a sufficiently inflammatory state of the skin or of the surface to justify you in taking antiphlogistic measures. Many cases will be cured by putting persons on low diet, and bleeding them from time to time. I do not know that in either lepra or psoriasis, mercury is of use. Lepra, however, is often a venereal affection, and so likewise is lichen; and in such cases you will fail in doing good unless you exhibit mercury. But when the disease is of a syphilitic character, the redness is of a coppery hue, and the spots are hard, in consequence of the disease approaching to a tubercular state. When you see that, no matter what the patient says, even if he aver that he has never been with a woman in his life, you had better give mercury; for on this subject patients will tell all sorts of untruths without the least hesitation. The hardness of the parts, and the copper hue, are sufficient to make you suspect that the lichen, lepra, or psoriasis, is of a syphilitic nature. But when you have ascertained that there is no decidedly inflammatory state sufficient to make you bleed the patient, or if you have already used antiphlogistic measures to reduce the inflammatory state, then other remedies may be employed, but of the mode of operation of which I am ignorant.

Now there are some which doubtless deserve all the character that has been given them, and one of these is dulcamara. I have seen so many cases give way under the persevering use of this medicine, that I have no doubt it is a remedy for the disease. A pint of the decoction may be given in the course of twenty-four hours. You may begin with two ounces three times a day, and then gradually increase the dose. Arsenic also has very great power over the affection. I have seen many cases yield decidedly when a person took arsenic. I think that these two are by far the most useful remedies in the disease. Some mention pitch as being serviceable, but I do not know that it has any particular power over the affection; if it have, I have not observed it, though I have made a patient swallow an ounce or two in a day; it is, however, perfectly harmless. The warm bath is very useful; but if there be much irritation of the skin the heat is unpleasant, and then I have not persevered with it. If the warm bath be used, it should be in a decided manner. The vapour bath is likely altogether to be more beneficial than the warm bath; but if either of them be used, it should be every day or twice a day. There is nothing weakening in it if patients do not keep themselves warm afterwards. The warm bath is seldom used to the extent that is required.

With respect to external applications, many persons wash the surface with a decoction of dulcamara, but you often find that the tar ointment is very useful; if, however, there be much irritation, it is not proper, and zinc ointment is better. Tar ointment is certainly one of the best applications that I am acquainted with in this disease, provided it is not of a syphilitic character, and you have employed antiphlogistic measures as long as the blood was buffy and cupped, or the patient's pulse justified it. Dulcamara, or liq. arsenicalis, should be united with it, as an internal medicine.

In regard to psoriasis, you will find antiphlogistic measures, particularly bleeding, of the highest use. Many cases will be cured by moderate bleeding and low diet. I do not know that dulcamara is of the same use in this form of the disease as in lepra, but I have seen many cases cured by sulphuric acid, and by various other acids, perseveringly given. It is singular how large a quantity of the acids you may give. One would imagine that, being chemical substances, you could not increase the quantity to a great amount. It is a common remark how you may increase the dose of narcotics; but we know that the susceptibility of the body to any sedative agent becomes less and less the more frequently it is employed; yet we should not suppose that it would resist chemical agents. We may however increase the dose of sulphuric acid, properly diluted, to a great extent; and I have frequently done so in psoriasis with the best effect.

But what I am anxious to impress upon you is, the importance of antiphlogistic treatment in all cases of this description,

where it is needed, and to impress upon you the necessity of looking out for inflammation.

When the skin cracks, you sometimes find greasy applications of great use in softening the affected part; but in a large number of cases they cannot be borne. You will find it of great use in the treatment of psoriasis, to prevent the patient from taking stimulants;—you will often find the disease kept up by stimulants taken as articles of diet. It is in vain to give acids, to bleed from time to time, or to give specific remedies, such as arsenic or dulcamara, unless the patient will submit to proper diet. If patients will take so many glasses of wine a day, they must expect that the disease will be so much the worse. Alkalies are said to be useful in this disease as well as acids, and I have no doubt that it is so. The treatment of the disease, so far as the parts are concerned, is empirical. I have no idea how arsenic and these other things can act; but the treatment by bleeding, local and general—by low diet, and by the use of the warm bath, is very rational.

[We think it right to state that Dr. Elliotson has not revised the proof of the above lecture: we believe, however, it will be found to be as correct as those which have preceded it.—E. G.]

LECTURES

ON

DISEASES OF THE EYE;

Delivered at the Birmingham Eye Infirmary,

By Richard Middlemore, Esq.

DISEASES OF THE CONJUNCTIVA.

In accordance with the arrangement I have proposed to adopt in the prosecution of my subject, I proceed to consider the diseases of the external tunic of the eye—the conjunctiva.

The conjunctiva is subject to a great variety of diseases, chiefly of an inflammatory kind; its situation renders it very liable to be injured by external agents, while the nature of its texture exposes it to all those diseases to which the mucous membranes in general are subject. I need not point out to you the anatomical characters of mucous membrane; but there are one or two circumstances connected with the anatomy of the conjunctiva to which I shall direct your especial attention. In the first place, you will remember that the entire conjunctiva presents a surface of considerable extent, commencing at the tarsal margin, constituting the internal surface of the eye-lid, and being afterwards reflected upon the eye-ball, the whole anterior surface of which it covers. That part of the conjunctiva which is extended over the cornea is very delicate and transparent, and in it the vessels which nourish the outer lamina of the cornea, ramify. Thus you will perceive why the conjunctiva is distinguished into three portions, named from the parts upon which they are situated—the corneal, the sclerotic, and the palpebral, portions of the conjunctiva.

Simple Acute Inflammation of the Conjunctiva.

By this term I mean an acute inflammation of the most simple kind, of the mucous membrane covering the anterior portion of the eye-ball and lining the lids, not possessing any particular character occasioned by constitutional peculiarity, or any specific disease of the system at large.

The first indications of this malady are, a sensation of itching and uneasiness of the eye, slightly increased vascularity, and a sense of stiffness on moving the lids upon the eye-ball—a sensation occasioned by an alteration and diminution of the conjunctival secretion, by which the motion of these parts is performed with more friction, and consequently with less facility, than usual; these constitute the first set of symptoms—symptoms so slight, indeed, that patients usually neglect them entirely, or attempt their removal by some trivial remedy. Presuming that the cause of irritation, whatever may be its nature, continues in operation, or that the remedies employed for the removal of the inflammation are inefficient, or unsuitable, these uneasy feelings become additionally troublesome; the vascularity of the conjunctiva is increased; many red vessels appear upon, and others may be seen situated within, the conjunctiva, towards the circumference of the eye-ball; the pain and the intolerance of light are augmented; the stiffness on moving the lids is extremely annoying; the edges of the eye-lids are covered by a glutinous secretion; and there is a sensation as though fine sand or dust had been insinuated beneath the lids, occasioned, as we know, by the inequalities of the contiguous surfaces of the conjunctiva, owing to the projection and sudden distention of its blood-vessels—a distention which is very considerable during the diastole of the arteries. Undoubtedly the extreme variability in the size of the blood-vessels of the conjunctiva (already in a morbidly enlarged condition), in accordance with their state of systole or diastole, must be considered the real cause of that peculiar sensation which patients under these circumstances experience, and which they sometimes characterize as

closely resembling the uneasiness they might be expected to suffer if sand or other rough particles had been insinuated beneath the lids.

Now if this state of things be not checked, the symptoms previously enumerated will all become aggravated in severity, and we shall have in addition, profuse lachrymation, increased conjunctival secretion, and chemosis—that is, a swelling around the cornea, owing to the enlargement of the vessels of the conjunctiva, and effusion into its texture, and between it and the sclerotica; the lining membrane of the eye lids will become thickened and tumid, projecting between them, and in severe cases producing a state of ectropium, and presenting an appearance similar to scarlet velvet. This swollen state of the conjunctiva will be very likely to produce sloughing of the cornea, and the consequent destruction of vision. At this period the deep-seated textures of the eye may become inflamed, and there will be added to the symptoms previously enumerated those of ophthalmitis—that is, inflammation of the tunics generally, a condition of things which is very likely to lead to suppuration of the eye-ball. The sloughing of the cornea in these cases is to be mainly attributed to the pressure of the effusion beneath the sclerotic portion of the conjunctiva, by which its vascular supply, and particularly that of its superficial layers, is compressed and diminished; at the same time the inflammation of the deep-seated tunics, originating in the general irritation to which the eye is subjected, and also from the contiguity of its delicate parts to those in a state of acute inflammation, terminates sometimes, as I have previously mentioned, in the effusion of a purulent fluid in the cavity of the eye; the crystalline lens loses its transparency and its vitality; the aqueous and vitreous humours become opaque, owing to the inflammation of those surfaces which secrete them, and unless they are discharged by the sloughing, or by a puncture of the cornea, they will, by increasing the distention of the globe, occasion the most intolerable suffering.

You know that when inflammation has proceeded to this extent, it destroys either altogether, or in a great measure, the absorbing surfaces of many parts of the eye, and renders them quite incompetent to take up those fluids which in their healthy state, and under circumstances of trivial disease or alteration, they were accustomed to remove. If, therefore, you wait in the expectation that the fluids effused into the globe will be absorbed, or delay to puncture the cornea, in the hope that it will spontaneously burst, you allow your patient to remain in a condition of agony—of indescribable severity, and, of course, you also permit the continuance of a risk of the occurrence of a destructive degree of inflammatory or irritative fever, and also the extension of inflammation and suppuration near a part of the highest importance to life—the brain.

At this stage the constitution will suffer more or less from this condition of the eye; there is, in fact, a certain degree of disturbance of the system; the pulse is quickened, the appetite diminished, the tongue loaded, and there will exist, in nearly every instance, a considerable degree of feverish disturbance, varying of course in its amount, in accordance with the previous state of the patient's health, and the susceptibility of his constitution.

This is a description of the disease when unchecked by timely and judiciously employed treatment: in ordinary cases it is speedily relieved, and the symptoms subside without leaving behind any injurious effects; this is the termination of the disease by resolution. It may, however, leave behind a diseased state of the meibomian glands (tinea), which may require a long course of treatment for its removal; it may terminate in chronic ophthalmia—that is, the acute stage may pass by, but the eye will continue irritable and weak, morbidly susceptible of atmospheric influence and strong light, and liable to become inflamed from a very slight cause; the vessels of the conjunctiva continue to be somewhat enlarged, and do not speedily regain their original size on the removal of the acute symptoms; it may produce a thickened and altered state of its own structure—the granular and cuticular state of the conjunctiva, as it has been termed; it may occasion deposition in, and beneath, that portion of the conjunctiva which covers the cornea, forming a troublesome opacity of that part; it may cause an extension of red vessels over the cornea—the vascular state of the cornea—which, when combined with the previously mentioned morbid product, is then termed pannus; it may (at least as some writers have asserted) leave behind a tendency to pterygium; or, finally, it may give rise to staphyloma, either of the cornea or of the sclerotica, or to hydrophthalmia. This is a mere enumeration of its effects and modes of termination, which I have mentioned here merely to render my subject more complete than it might be considered to be without this recital of its modes of conclusion, and its occasional products. Some of the last-named effects are, of course, produced by the extension of the disease to other textures. Many of the occasional effects of this disease to which I have just adverted, will furnish us with subjects for separate consideration at a future part of these lectures.

Diagnosis.—This form of inflammation will be distinguished at its commencement by the mildness of its symptoms, and the absence of much constitutional disturbance; there will be little pain, and scarcely any aversion to light; the blood-vessels will be of a bright scarlet colour, superficial in their situation, least abundant near the cornea, and scarcely at all influenced by the motions of the globe, but will be governed by the movements of the eye-lids: if you move the loose conjunctiva in various directions upon the eye-ball, the enlarged vessels will be moved also. You will experience no difficulty whatever in detecting the distinction to which I am now referring, by merely fixing the conjunctiva by pressing the lower lid upon the globe, while the patient at the same time moves the eye freely in various directions; and, lastly, you will observe that in severe cases, the conjunctival vessels project, and elevate that portion of the conjunctiva in which, or between which and the sclerotica, they may be placed.

In stating that the vascularity of the conjunctiva is chiefly situated at the periphery of the eye-ball, I ought to mention that this only refers to its earlier stages, for when the disease is fully developed in its most acute form, the conjunctiva is an entirely red, and almost uniformly red surface. The vessels are first merely a few enlarged trunks towards the periphery of the globe; by degrees they become more numerous, and ramify very extensively, gradually approaching the cornea, until, as has been stated, the whole sclerotic portion of the conjunctiva acquires a florid appearance. These are some of the means by which you would be enabled to distinguish inflammation of the conjunctiva from that of the sclerotica; and, if you contrast them with the phenomena usually connected with inflammation of the deeper-seated textures, you cannot, I think, form an inaccurate diagnosis: for instance, in sclerotitis you will have not smarting merely, but severe pain, profuse lachrymation, and extreme intolerance of light: the blood-vessels will assume a pink appearance, from the circumstance of their being seen through the interposed conjunctiva; there will be only a slight apparent increase of vascularity, and the majority of the vessels will be situated in a circle around the margin of the cornea, and not, as in the former case, chiefly at a distance from it, and they will also move with the globe of the eye, and not with the conjunctiva covering it.

As the other forms of acute inflammation of the conjunctiva are characterized by the quantity or quality of the discharge secreted from the inflamed surface, or by other sufficiently distinctive symptoms, I have not considered it necessary to direct your attention to the various circumstances by which they are distinguished from the disease now under consideration; indeed they can only be confounded by an extremely ignorant, or culpably inattentive person.

Causes.—The causes of this description of inflammation are very various: it may be produced by small tumors at the edge of the eyelids, an inverted condition of the tarsal cartilage, irritation from the friction of one or more of the ciliæ, which may be occasioned either by their improper inclination towards the globe, or by their original malposition. Foreign substances, by destroying the smoothness and equality of those parts of the ocular and palpebral surfaces which move upon each other, growths beneath or from the surface of the conjunctiva, the irritation of minute particles of dust, sand, or metal, keen winds, suddenly contrasted temperatures, and excessive use of the organ, particularly by a bright artificial light, such as a gas-light, may also excite inflammation of this membrane: in short, any thing capable of mechanically irritating this part may be classed among the causes of its inflammation. And lastly, various constitutional defects, or sympathy with various states of the constitution, give rise, on many occasions, to conjunctival inflammation—such as scrofula, prolonged lactation, various disordered or diseased conditions of the uterine system, and of the alimentary canal; and to these causes of inflammation of the conjunctiva may be added various eruptive and irritable states of the skin, and the recession of a cutaneous eruption, or the sudden healing of a wound, or the suppression of some long accustomed and habitual discharge.

Treatment.—We now proceed to the treatment of this disease. You will remember, that after having described the earliest symptoms by which its existence was known, I proceeded to point out those phenomena which characterized its unchecked progress.

When called to a case of this description during the existence of the first set of symptoms, we can most certainly control it at once (particularly if it do not depend on any constitutional cause), by bleeding from the arm or by cupping, if the patient's strength will justify us in so doing; by the use of active purgatives, such as calomel and jalap; by directing the patient to bathe the eye frequently with a little Goulard water; to exclude all brilliant light from his apartment; and to lessen the quantity and lower the quality of his food; not omitting, of course, to ascertain, and if possible to remove, the original cause of

the irritation, for if this be neglected the cure may be impracticable, or at least unnecessarily protracted, and relapses will almost certainly occur. I lately saw a young man who had a severe attack of conjunctivitis, which did not yield to the treatment recommended by his surgeon, and, on perceiving a swelling of the upper lid, I everted it, and removed a small portion of a twig, which had remained there ever since he had received the blow which gave rise to the inflammation.

But, to return, if we do not see the case until the symptoms are at their height, and chemosis is commencing, our treatment must be at once active and decisive. If you are content with applying a few leeches and relaxing the bowels by aperient medicine, vision will be certainly injured, and probably destroyed. You must commence your treatment by largely depleting the system, by bleeding from the arm, repeating the operation as frequently as may be consistent with the strength of your patient, and the effect of the previous bleedings upon the eye; at the same time the bowels must be well acted upon, by the administration of calomel and jalap; the eye must be kept cool by Goulard water, or some similar application; all exercise of either organ must be proscribed; light must be in a great measure excluded from the patient's apartment; and the diet must be limited to the most simple and unstimulating aliments.

By these means you will generally *arrest* the inflammatory process: should this be the case, you may apply a number of leeches beneath the lower eye-lid, and excite counter-irritation near, but not close to, the diseased organ. You will find the application of a blister to the nape of the neck a useful form of counter-irritation; and that situation is, perhaps, under these circumstances, as good as any. It is customary with some practitioners to employ stimulants at this stage—such as the wine of opium, a solution of nitrate of silver, or the sulphate of zinc; but I cannot recommend this practice as one generally necessary or uninjurious. Unless the vessels of the conjunctiva have been much distended by long-continued inflammation, they will usually regain their original magnitude on its subduction, without the aid of such irritating applications, and without leaving behind that irritable state of the eye which they have always a tendency to excite, and, in some instances, most certainly produce. You will imagine that so delicate an organ as the eye will not, when much inflamed, bear with impunity remedies which, in its healthy state, would seriously injure and severely inflame it.

It was for the removal of this state of things that Mr. Ware so strongly recommended the thebaic tincture; but it is scarcely necessary to remark that this stimulant must be considered a mere palliative and subordinate remedy. If you employ it to the exclusion of active depleting measures, you may lose that time and those opportunities of subduing the disease which may not again occur.

I have told you that Mr. Ware (who had formerly a most extensive experience in the treatment of diseases of the eye, and who wrote a book on what he quaintly termed "The Ophthalmy,") urgently advised the use of the thebaic tincture (a preparation for which the tinctura opii was afterwards substituted in our pharmacopœia), and was at great pains to explain to the profession the mode in which it should be insinuated beneath the lids, and the quantity to be employed for that purpose. He objected to the custom of dropping several drops upon the eye, from what he termed a considerable height, and recommended that one drop only should be placed in the inner corner of the eye, and allowed to flow gently and gradually over its surface. He recommended this remedy, nearly indiscriminately, in every state and stage of almost every variety of inflammation of the eye, and was consequently compelled to admit that there are some cases in which its employment occasions severe symptoms, and requires to be omitted until the irritation it has produced has been subdued by antiphlogistic and other necessary measures; when its use may be resumed. Such a mode of using a remedy is, of course, highly injudicious; and it is by no means justifiable to employ this, or any other means of relief, without a due discrimination of the case to which it is suited, and the proper time at which it may be safely and beneficially employed.

You will generally find these measures sufficient to effect a cure without the aid of mercury, which, in inflammation of this texture, is seldom necessary, although its utility in many of the forms of inflammation of the deep-seated textures is established beyond the shadow of a doubt.

There is another stage, concerning the treatment of which I have as yet said nothing—namely, when the disease has been either not treated at all or treated by inefficient or inappropriate means, and has been permitted to proceed to an extent adequate to produce the state of chemosis and its concomitant symptoms, formerly described. I do not know that you can, with advantage, much vary the plan of treatment recommended for the relief of the acute stage. You must bleed to as great an extent as the patient's strength will permit, and, in addition to the other mea-

sures then suggested, employ the alum or some other astringent lotion, and freely scarify the tumid conjunctiva. You will in this way obtain a certain quantity of blood from the inflamed part; you will lessen the compression upon the vascular supply of the cornea, and diminish that painful tension of the eye-lid which the swollen state of the conjunctiva occasions. After these scarifications have been made, you will find it useful to instil into the eye a few drops of a solution of the nitrate of silver (about two grains of the nitrate to twelve drachms of distilled water); it would seem to constringe the loose conjunctiva, and to diminish its size. Mr. Ware has said that the vapour of æther, applied to the surface of the eye, has a very beneficial influence in the removal of chemosis; and you may adopt his advice if you wish to trifle with disease rather than cure it.

It may even be necessary to scarify the eye-lid if the chemosis be not promptly subdued, on account of the pain excited by the distention of their vessels by the compression produced by the elargement of the conjunctiva, and the consequent risk of mortification of the palpebral integument. If the cornea assume a dull ashy appearance, and the pain and distention of the globe, the hemicrania, and the constitutional symptoms render it probable that there is ophthalmitis present, which is producing a purulent effusion within the eye-ball, the cornea must be freely divided, so as to permit the escape of the humours and effused fluids, and remove that tense condition of the globe, which, owing to the strength of its tunics, might not be effected by natural efforts alone until the patient has experienced the most agonizing torment, and even hazarded his life. You would not, in this case, judge it requisite to reduce the system, for it almost invariably happens, that when the disease has proceeded so far, the powers of the system are depressed and the patient is suffering from the *effects*, rather than from the *actual existence*, of inflammation. Your antiphlogistic remedies cannot now preserve the eye, but may increase the langour and irritability of a system already exhausted by pain and depressed by active treatment. But it is impossible for me to lay down any precise rules for your guidance in every instance; the exercise of your judgment alone can, in many cases, direct you when to deplete and when to support and tranquillize the system; but remember it is most important to decide correctly.

As scarifications have been recommended for the removal of chemosis, allow me to call your attention to the varieties of chemosis to which this operation is suited, and to describe the mode of performing it. Chemosis is of two kinds, the active inflammatory and the mild inflammatory, or the lymphatic and the œdematous chemosis. The former is, of course, its severest form, and occurs in connexion with acute inflammation of the conjunctiva in strong plethoric subjects. It is distinguished by its firmness and the greater degree of uneasiness it excites; and you will find that it consists chiefly of enlarged blood-vessels and lymph effused into the cellular membrane by which it is connected with the sclerotica. The mild inflammatory chemosis, on the contrary, occurs in feeble persons, or in connexion with a milder degree of conjunctival inflammation; it is loose and flabby in its texture, is more voluminous than the preceding variety, and extends generally so far over the cornea as nearly to conceal it entirely. It is attended with scarcely any uneasiness, and, if it be examined, it will be seen to be composed chiefly of serous effusion into the cellular texture immediately beneath the conjunctiva.

These varieties of chemosis differ in degree—for instance, there may be merely a tumid condition from enlargement of vessels, or there may be, in addition, a slight or a more considerable amount of serous infiltration into the cellular structure connecting the conjunctiva to the sclerotica; or the chemosis may chiefly consist of a deposition of lymph into the cellular web just mentioned. The effusion of blood beneath the conjunctiva is quite distinct from the morbid product to which your attention is now directed. I shall not enlarge upon this subject by alluding at all in detail to the changes occasionally wrought in the conjunctiva, by the continuance or organization of the lymphatic portion of active inflammatory chemosis; but you will be aware, from your knowledge of general pathology, that deposited and partially organized lymph undergoes various subsequent changes, which constitute a source of interesting investigation and inquiry to the zealous pathologist.

Let me for a moment allude to the object which the effusion termed chemosis is intended to fulfil, to the effects it sometimes produces, and to its treatment. The inflamed conjunctiva has a mode of relieving itself externally by various secretions, as I have previously mentioned, and it possesses also the means of lessening the plenitude of its vessels, and consequently of limiting its inflammatory excitement, by effusion from its sclerotic aspect; which effusion, in conjunction with other occurrences, is termed chemosis. This deposition separates the inflamed membrane from the sclerotica and from the margin of the cornea, and in this way generally prevents the extension of inflammatory action

to those parts; but if the chemosis continues, there is frequently produced gangrene of the external layers of the cornea, either from an excessively inflamed state of that portion of the conjunctiva which covers and supports it, or from the strangulation of those vessels which pass from that part and thence to the cornea. This incipient gangrene is very likely to spread in a part so feebly organized and so unfavourably circumstanced as the cornea, when in a state such as has been described; and, accordingly, the whole of that tunic not uncommonly sloughs.

The operation now to be described is suited to both forms of chemosis. You request an assistant to elevate the upper lid, and, standing in front of the patient, you depress the inferior palpebra with the left hand; you then draw an instrument similar to that invented by Mr. Wardrop (or, in its absence, a lancet) gently along the surface of the tumid conjunctiva. You need not be apprehensive of scarifying too deeply, for the effusion beneath the conjunctiva will prevent the instrument from injuring any part beneath it, and it will be quite necessary to divide that membrane completely, inasmuch as without such division you can neither relieve its tension nor sever many of its enlarged vessels, nor discharge the more fluid portion of the effused matters.

ON THE LAW OF THE DIFFUSION OF GASES.

By Thos. Graham Esq. M.A. F.R.S.E.
Professor of Chemistry, Andersonian University, Glasgow.

[Concluded from page 143.]

1. *Diffusion Volume of Hydrogen Gas.*

I shall in this paper adopt the specific gravities of the gases generally received in this country. Of hydrogen, the specific gravity is 0·0694 (air = 1), of which number the square root is 0·2635. Now, according to our law, 1 volume hydrogen should be replaced by 0·2635 air. But to have the replacing volume of air = 1,

$$0{\cdot}2635 : 1 :: 1 : 3{\cdot}7947;$$

or, $\frac{1}{0{\cdot}2635} = 3{\cdot}7947$; that is, 1 air should replace 3·7947 hydrogen. With the specific gravity of hydrogen adopted by Berzelius, namely, 0·06885, the equivalent diffusion volume of hydrogen is 3·8149.

In a diffusion tube standing over water, temperature 65°, 88 volumes hydrogen were replaced by 26 air; 84 hydrogen by 25 air; and in another tube, 130 hydrogen by 38 air. The quantity of return air is here related to the hydrogen diffused, as 1 to 3·38, 3·36, and 3·42, numbers which approach to, but fall short of, the theoretical diffusion volume of hydrogen, namely, 3·79. But the hydrogen in these experiments was saturated with vapour at 65°, which would make its density 0·0809, and reduce its diffusion volume to 3·5161; while the air without, being comparatively dry, would be somewhat expanded *after* it entered the diffusion tube, by the ascent of vapour into it. This would occasion the quantity of return air to appear greater than it should be; but it is difficult to find elements for a proper correction, as not only the quantity of vapour in the atmosphere must be taken into account, but also the hygrometric state of the plug itself. The increased return air, however, evidently lowers the diffusion volume of the hydrogen gas.

With the view of increasing the capacity of the instrument, and the number of its divisions, and of obviating the interference of vapour, the mode of performing the experiment was varied. On a tube, four-tenths of an inch in diameter, a bulb of two inches in diameter was blown. The tube above and below the bulb was graduated into two-hundredths of a cubic inch. The upper end of the tube was closed by stucco, as in the case of the simple diffusion tube. The general mode of proceeding was as follows:—The bulb being sunk in water with the air syphon in it, the whole air was withdrawn, with the exception of a certain quantity, which was noted, and the instrument filled up with newly-made hydrogen gas. As soon as it was filled, it was placed in a glass jar of about the same height, with a little water left in the bottom, and in proportion as the water rose in the upper tube, from the subsequent contraction, the jar was filled up by repeated additions of water, so as to keep the surface of the water, within and without the tube, as nearly as possible at the same level. With the view of having the external air in a constant state in regard to humidity, means were taken to saturate it.

A small cone of damp paper was inverted, like an extinguisher, over the upper part of the instrument; the jar containing the instrument was placed on the shelf of the pneumatic trough, and a bell jar with an opening at the top, which could be shut at pleasure, inverted over the whole. The return air must, therefore, have been in the same state, in regard to humidity, as the hydrogen itself. Aqueous vapour would diffuse neither outwards nor inwards, as it existed in the same proportion on both sides of the plug; but dry hydrogen only would be exchanged for dry air, in the proportion of their equivalent diffusion volumes.

As the quantity of hydrogen and of return air is amplified in the same proportion by vapour, provided the temperature be the same at the beginning and end of the experiment, it is unnecessary to know the absolute quantity of vapour in either case, in determining the diffusion volume of hydrogen. We may simply divide the gross amount of hydrogen gas diffused by the gross amount of return air, the quotient is the diffusion volume of hydrogen.

The results of five experiments, with the same instrument, into which 1085·7 measures hydrogen were introduced, are, in one view,

Measures of Return Air.	Diffusion Volume of Hydrogen.
285·1	3·808
286·1	3·795
278·4	3·900
279·1	3·890
282·2	3·847
Mean, 282·2	Mean, 3·848

New hydrogen gas was made for each experiment by the moderate action of dilute sulphuric acid on zinc, and it was collected in the diffusion instrument from the beak of the retort. The observations could not be made with so much accuracy as to entitle us to place any reliance on more than two decimal places of the calculated diffusion volumes. A great variety of experiments were performed on the diffusion of hydrogen with the diffusion bulbs employed above, and several others of similar construction, principally with the view of discovering the cause of the slight variations in the results, and why the quantity of return air was pretty uniformly somewhat less than the theoretical quantity, which has the effect of increasing the proportion of the hydrogen diffusion volume. The results in the case of coal gas, carbureted hydrogen, and olefiant gases, were found to be affected in the same manner. The cause was eventually found to be the unequal frictional resistance these gases experience in passing through the pores of the stucco, compared with air.

The same volume of different gases entered an exhausted receiver through the pores of a mass of stucco, in the times expressed in the following table, under the same pressure, or beginning at a pressure of 29 inches mercury, and terminating with a pressure of 27 inches:

	Min.	Seconds.
Air, dry	10	0
Air, saturated with moisture at 60 deg.	10	0
Carbonic acid	10	0
Nitrogen	10	0
Oxygen	10	0
Carbonic oxide	9	30
Olefiant gas	7	50
Coal gas	7	0
Hydrogen	4	0

Dried bladder answers for shewing the diffusion of hydrogen when stretched over the open end of the tube receiver. The diffusion, however, through a single thickness of bladder, is effected at least twenty times more slowly than through a thickness of one inch of stucco. While, on the other hand, either air or hydrogen, under mechanical pressure, passes more readily through bladder than a great thickness of stucco. Goldbeaters' skin is even more permeable by gases under a slight pressure than bladder, and less suitable for diffusion.

The superior aptitude of stucco for exhibiting the unequal diffusion of gases of different densities, seems to depend upon its pores being excessively numerous, but exceedingly minute, making in the aggregate a considerable channel. In the bladder, or goldbeaters' skin, the pores I suppose to be few in number, but wide; making, however, when added together, but a small channel. Air passes through them but little impeded by friction.

Dry and sound cork answers exceedingly well as a substitute for the stucco-plug. The diffusion takes place slowly, but is not apt to be deranged by a slight mechanical pressure. So do thin laminæ

of many granular minerals, such as the flexible magnesian limestone, &c.; charcoal also, and woods, if not too porous, may be applied to the purpose.

It might occur, in explanation of our experiments with the diffusion instrument, to take Mr. Dalton's hypothesis, and suppose, in the case of hydrogen, the external air to be a vacuum to the hydrogen, and the hydrogen a vacuum to the air, and that the *inequality* of the diffusion depends upon the hydrogen *being least resisted in passing through the plug*. The experiments on the permeability of the stucco by gases under pressure, above detailed, were projected with a view to settle this point among others; and they are evidently incompatible with such an application of the theory, for hydrogen passes 2·4 times more swiftly, and not 3·8 times, as in the diffusion of experiments. Carbonic acid, too, permeates the plug, under pressure, as rapidly as air does, or even somewhat more rapidly, for our results inclined to this side rather than to the other; whereas carbonic acid diffuses through the plug more slowly than air does, or is replaced by more than an equal volume of air, as will presently appear.

Those experiments previously narrated, are perhaps sufficient to establish the law in regard to hydrogen, particularly when we find it hold in the case of other gases.

As hydrogen is a very light gas, I was anxious to establish the law also in regard to a heavy gas, such as carbonic acid.

2. *Diffusion of Carbonic Acid Gas.*

The most satisfactory experiments with carbonic acid gas were performed by confining it over a solution of common salt, saturated in the cold, which absorbs this gas very slowly, and, instead of the diffusion instrument with bulb, a long diffusion tube was found most suitable.

In one experiment, 176·6 volumes carbonic acid were replaced by 217·6 air; and of course an ultimate expansion of 41 measures occurred. In another 201 gas by 246 air.

In a third, 169 gas by 206 air.

By theory, 1 volume air should replace 0·809 vol. carbonic acid; and by these experiments, 0·812, 0·813 and 0·816 vol.

The following table exhibits a summary of the results in the case of the preceding and other permanent gases which can conveniently be submitted to diffusion. Vapours cannot be rigidly examined, as they are all condensible in the pores of the stucco.

Table of Equivalent Diffusion Volumes of Gases; Air = 1.

	By Experiment.	By Theory.	Specific Gravity.
Hydrogen	3·83	3·7947	0·0691
Olefiant Gas	1·0191	1·0140	0·972
Carbonic Oxyde	1·0149	1·0140	0·972
Nitrogen	1·0143	1·0140	0·972
Oxygen	0·9187	0·9487	1·111
Sulphureted Hydrogen	0·95	0·9201	1·1805
Protoxide of Nitrogen	0·82	0·8091	1·527
Carbonic Acid	0·812	0·8091	1·527
Sulphurous Acid	0·68	0·6708	2·222

In the diffusion volumes of oxygen, nitrogen, and carbonic oxide, the correspondence between theory and experiment is as close as could be desired. Indeed, admitting our law, I believe that the specific gravity of these gases can be determined by experiments on the principle of diffusion, with greater accuracy than by the ordinary means.

The density of any gas diffused into air, both being in the same state as to aqueous vapour, is obtained by the formula $D = \left(\frac{A}{G}\right)^2$; where G is the volume of gas submitted to diffusion, and A the volume of return air.

A peculiar advantage of this mode of taking the specific gravity of gases, besides its simplicity, is, that we can operate upon a most minute quantity of gas: it is possible to come within 100th of the specific gravity, operating

upon no more than one cubic inch of gas.

I had occasion to remark, more than once, a singular accident to the stucco plugs. After being disused for some days or weeks, and left in the interval exposed to the air, which might be either dry or damp at the time, the plugs occasionally, on a new trial, did not permit diffusion to take place through their pores, at least immediately. Hydrogen, however, always opened a passage in the course of two or three minutes, and then the diffusion proceeded as rapidly as ever. Carbureted hydrogen, and the other gases, often required a longer period. A slight heat restored the action of the plug. The obstruction could not be attributed to moisture, nor to any thing but dust.

It may be mentioned, that there was nothing peculiar in a mixture of two gases, in the proportion of the numbers expressing their diffusion-volumes;—nothing that could be considered an indication of mutual saturation.

Evaporation, or the elevation of vapour from a liquid into air, or any other gas, comes now to be explained on the principles of diffusion. The powerful disposition of the particles of different gaseous bodies to exchange positions, may as effectually induce the first separation of vapour from the surface of the liquid, as a vacuum would do. Once elevated, the vapour will be propagated to any distance, by exchanging positions with a train of particles of air, according to the law of diffusion. The length to which this diffusion proceeds, in a confined portion of air, is limited by a property of vapour, namely, that the particles of any vapour condense when they approximate within a certain distance. Hence, the quantity of vapour which rises into air, has the same limit as that which rises into a vacuum, and is the same.

I may be allowed to mention an application of the law of diffusion, in explanation of the mechanism of respiration. The cavity into which air enters during respiration, consists, first, of a large tube, the windpipe; secondly, of smaller tubes, into which the windpipe diverges; and, thirdly, of a series of still smaller tubes, diverging from the last, themselves ramifying to an indeterminate extent, till at last the tubes cease to be of sensible magnitude, but are believed to terminate in shut sacs. The capacity of the whole cavity cannot easily be determined, but we may estimate it at 300 cubic inches. In a natural expiration, about 20 cubic inches, or $\frac{1}{15}$th of the contents are thrown out, from the application of a general pressure to the whole. But it is evident, that these 20 cubic inches will be the 20 cubic inches nearest the outlet, or the contents of the larger tubes. The contents of the second-sized tubes will advance at the same time into the largest tubes, but no further, and will recede again into their original depositories on the next inspiration, which will fill the larger tubes with fresh air; which identical quantity will again be expelled in the next expiration. This illustration is perhaps too strongly stated; but it is evident, that in ordinary respiration, the slight mechanical compression will have little or no effect in emptying the most distant tubes, or the ultimate air-cells, of their contents. The bulk of the air, also, is not altered, during respiration, although, for a quantity of oxygen, carbonic acid gas is substituted. This substitution, which is the great end of respiration, undoubtedly takes place most abundantly, in the minute and distant air-cells, which present the largest surface to the blood; and the carbonic acid there produced, must be moved along the smaller tubes by the diffusion process, (which we know to be extremely energetic, and also inevitable), till it is thrown into the larger tubes, from which it can be expelled by the ordinary action of respiration. But the action of diffusion is always twofold: at the same time that carbonic acid is being carried outward from the air-cells, oxygen is carried inwards in exchange, and thus the necessary circulation kept up throughout the whole lungs.

Farther, by a forced expiration, from 160 to 178 cubic inches may be expelled, after which, there still remain in the lungs about 120 cubic inches, which are not under the control of the respiratory action.

There can be no doubt that much of this quantity occupies constantly and permanently the most minute tubes and air-cells, for it can scarcely be withdrawn by means of the air pump. Now the question has arisen, how these ultimate tubes and air cells are so powerfully inflated; for they are not distended by the action of muscular fibre, of which

they are known to be destitute. This state of distention must be highly useful by exposing surface; and the law of diffusion enables us to account for it. The heavy carbonic acid which these minute cells may contain, is not merely exchanged for oxygen, but for a larger volume of oxygen, in the proportion of the diffusion-volumes of carbonic acid and oxygen, namely, 81 carbonic acid are replaced by 95 oxygen. The resistance to passage through the most minute tubes, is overcome by the diffusion action, as in the case of the pores of the stucco-plug, and there follows a tendency to accumulation on the side originally occupied by the carbonic acid. This accumulation is limited by the increased facility with which the air-vessels can empty themselves mechanically of a portion of their contents, from their distended state.

In the law of diffusion of gases, we have, therefore, a singular provision for the full and permanent inflation of the ultimate air-cells of the lungs.

But it is in the respiration of insects, that the operation of this law will be most distinctly perceived. The minute air-tubes accompanying the bloodvessels to every organ, and like them ramifying till they cease to be visible under the most powerful microscope, are kept distended during the most lively movements of the little animals, and the necessary gaseous circulation maintained, wholly, we may presume, by the agency of diffusion.

In regard to the terms of the law of diffusion: "The diffusion, or spontaneous intermixture of two gases in contact, is effected by an interchange in position of *indefinitely minute volumes of the gases.*" My experiments, published on a former occasion, on the diffusion of mixed gases (*Quarterly Journal of Science*, Sept. 1829), afford the first demonstration of the fact, that diffusion takes place between the ultimate particles of gases, and not between sensible masses, and therefore that diffusion cannot be the result of accident. For, in the case of a mixture of two gases escaping from a receiver into the atmosphere, by apertures of 0.12 and 0.07 inch in diameter, it was not so much of the mixture which left the receiver in a given time, but a certain proportion of each of the mixed gases, independently of the other, corresponding to its individual diffusiveness. The same separation of mixed gases occurred in diffusion through the pores of stucco, or the fissure of a cracked jar.

"Which volumes are not necessarily of equal magnitude, being in the case of each gas, inversely proportional to the square root of the density of that gas." This may be demonstrated, when different gases communicate by very narrow channels, or by very small apertures, and when inequality of pressure is guarded against. In the case of a gas communicating with the air by a wide aperture, on the other hand, although the diffusion or intermixture takes place precisely in the same way, still the result is different; for where a contraction takes place from the process of diffusion the air flows in mechanically through the aperture, wholly unresisted, and makes up the deficiency. A gas, however, of large diffusion-volume escapes, in these circumstances, *in a shorter time* than a gas of small diffusion-volume. Indeed, it was the conclusion of the former paper, that gases diffuse more or less rapidly according to some function of their densities, "apparently inversely as the square root of their densities." The advantage, in illustrating the process of diffusion, of minute apertures or channels of communication, such as we have in the stucco-plug, depends upon the circumstance, that when a contraction or expansion takes place in the gaseous contents of a diffusion-instrument, any current in an outward or inward direction is prevented by frictional resistance; so that the simple result of diffusion is exhibited, not complicated by the effect of any other force.

The law at which we have arrived (which is merely a description of the appearances, and involves, I believe, nothing hypothetic), is certainly not provided for in the corpuscular philosophy of the day, and is altogether so extraordinary, that I may be excused for not speculating farther upon its cause, till its various bearings, and certain collateral subjects, be fully investigated.

APPEARANCES OBSERVED IN A CASE OF DOUBLE UTERUS, IN WHICH *Impregnation had taken place.*

By Robert Lee, M.D. F.R.S.*

[With an Engraving on Wood.]

On the 2d of August, 1831, I was present with Dr. Sims and Mr. Morley, of Leicester Square, at the examination of the body of a woman who had died eight days subsequent to parturition, from inflammation of the peritoneum, appendages and veins of the uterus. She had previously borne several living children, but nothing unusual occurred during labour on any of these occasions. The uterine organs were found on dissection to be malformed, and several remarkable appearances were observed in their structure, of which the following is a short history.

The body of the uterus was cleft as it were down the middle, from the fundus to the cervix, so as to form two lateral halves, which opened into the cervix, like the uterine cornua of most mammiferous animals. The cervix, os uteri, and vagina, presented the ordinary appearances observable at the same period after delivery. The right cornu had contained the fœtus, and it did not differ perceptibly in its form and size from the uterus in common cases a week after delivery. Coagula of the fibrine of the blood were found closing the semilunar orifices of the uterine sinuses, and the whole inner surface was lined with rough irregular flakes of deciduous membrane, or a layer of the fibrine of the blood. One ovarium and one Fallopian tube were connected with this cornu, and the same was the case with the unimpregnated cornu. Both ovaria were enlarged, but the right was much larger than the left, and contained a corpus luteum. In the left ovarium no corpus luteum existed.

The left cornu was about the ordinary size of the unimpregnated uterus. Its parietes, when divided, were observed to be unusually soft and vascular, and its internal surface was everywhere coated with a delicate and beautifully formed deciduous membrane. At the opening of the cornu into the cervix, the deciduous membrane formed a shut sac, but it presented a smooth circular opening at the uterine orifice of the Fallopian tube. The fibres of this membrane as they approached the opening of the tube, ran in a converging direction like radii to the centre of a circle, and passed into the opening, leaving it completely pervious, although of the ordinary small dimensions. The distance to which the fibres of the deciduous membrane extended into the Fallopian tube could not be clearly ascertained, nor was it positively determined if the whole extent of the canal of the tube was open.

In the works of different authors, various irregularities in the formation of the human uterus have been described, under the terms bilocular, bicorned, bifid or double uterus, in all of which, without a single exception, the uterine appendages have been simple, or have consisted of one ovarium and one Fallopian tube annexed to each cornu of the uterus, and not of two ovaria and two Fallopian tubes, as the term double uterus would seem to imply. In the examination of a great number of children at the Maternité of Paris, the division of the uterus, as in the case now related, was often met with. Professor Chaussier has described the case of a woman who was delivered in the Maternité of her tenth child, in whom it was found after death, that the right side of the uterus existed, with one ovarium and one Fallopian tube*. Littre, in dissecting the body of a little girl, found the vagina divided by a fleshy perpendicular septum into two equal cavities. Vallisneri relates the history of a woman who was poisoned by cantharides, in whom two uteri were found to exist, one of which opened into the vagina, the other into the rectum†. M. Cassan has referred to numerous other examples of similar malconformations of the uterine organs, and to those more particularly which are contained in the Memoirs of the Royal Academy of Sciences‡. In the Museum of the Royal College of Surgeons, there is a specimen of bifid unimpregnated uterus, and another was preserved in the collection of Mr. Brookes, in which the fun-

‡ Recherches sur les cas d'Uterus Double et de Superfœtation; par A. L. Cassan. Paris, 1828.

dus, cervix, and os uteri, were all divided by a thick septum.

The whole of these malformations have been reduced to the four following varieties, which have been accurately delineated by Messrs. Lauth and Cruveilhier. 1st, Where the uterus and vagina are separated into two cavities by a septum running in the direction of the mesial line, while the external configuration of the uterine organs presents nothing unusual. 2ndly, Where the fundus and body of the uterus were divided into two cornua; the cervix, os uteri, and vagina, remaining in the normal state. 3dly, Where the uterus is bifid, as above, while the cervix and vagina are also divided by a septum. 4thly, Where the vagina forms a single canal, with a double os uteri.

All these deviations from the natural formation of the uterus, have been referred by Meckel to a suspension of the development of the parts, in consequence of which the uterine organs manifest, during the whole of life, some of the conditions peculiar to the embryonic state. This principle, indeed, explains some of these varieties of malformation, as, for example, those which have been classed by Blumenbach under his genus of monstra per defectum; but in the cases where redundant parts are met with, it is wholly inapplicable, and physiologists cannot at present account for these in a satisfactory manner.

Morand, Bartholin, Tiedemann, Ollivier, and Dr. Blundell, relate cases of double uterus, in which impregnation had taken place, and the fœtus had been retained till the full period. None of these authors have alluded to the presence of a deciduous membrane in the unimpregnated cornu of the uterus; but that it is formed in all similar cases, appears probable from this circumstance, that in the gravid uterus of the lower animals, the membrane which surrounds the product of conception, invariably occupies the whole inner surface of both cornua.

The disposition of the deciduous membrane, in the case I have now related, must have rendered superfœtation, or the conception of a second embryo during gestation, impossible, and its history tends entirely to overturn the recent speculations of M. Cassan also, on the possibility of superfœtation where a double uterus exists. Menstruation must have been equally impossible in this case, as in ordinary pregnancy, where the inner surface of the uterus is lined with decidua.

The most remarkable example of impregnated double uterus which has perhaps ever occurred, is the following, which has been recorded by Dr. Purcell, of Dublin, in the Philosophical Transactions, vol. lxiv. p. 474:—

"Last summer (1773) the body of a woman who had died in labour, in the ninth month of pregnancy, was dissected in the Anatomical Theatre of Trinity College. Upon opening the abdomen, an uterus appeared of such a size and form as is usually observed at that period. It contained a full grown fœtus, but was furnished with only one ovarium, and one Fallopian tube, which were situated on the right side. On the left was placed a second uterus, unimpregnated, and of the usual size, to which the other ovarium and tube were annexed. But these two uteri were wholly distinct and separated from each other, except at the lower extremity of their necks, where their union extended a quarter of an inch, and an acute angle was formed between. There was nothing extraordinary in the formation of the external parts of generation; but from each side of the meatus urinarius, a membrane ran downwards, and the two having comprehended this orifice between them, were joined together a little below it, so as to form, by their union, a septum or mediastinum, which taking the remainder of its origin from all that hard ridge called the superior columna, so as to extend from the entrance of the vagina as far backwards as its posterior, and thus divide it into two tubes of nearly equal dimensions. But each of these did not lead to the womb of its own side; for the right vagina became gradually wider as it ran backwards, and at last was so far dilated as to comprehend within its circumference the orifices of both uteri, while that on the left side having taken an oblique direction, ended in a cul-de-sac or cæcum."

The preparation of the parts thus described, was afterwards purchased by Mr. Hunter, and is now in the museum of the Royal College of Surgeons in London, and forms one of the most valuable specimens in the collection. Dr. Purcell having omitted to lay open and describe the condition of the unim-

pregnated cornu, I applied to the Board of Curators for permission to examine this part of the preparation, to determine if it were lined with a deciduous membrane, and if the uterine orifice of the Fallopian tube were open. Permission was readily granted, and the necessary examination was made in the presence of Mr. Clift and Mr. Owen, but no trace of deciduous membrane could be detected, and even the internal membrane of the left cornu appeared to be wanting. It is impossible now to determine whether these membranes were removed artificially when the part was laid open by Mr. Hunter, after it came into his possession, or if they subsequently disappeared from decomposition during the lapse of fifty-nine years. Prior to the examination, the impression upon Mr. Clift's mind was, that when the left cornu was first laid open, a deciduous membrane had been discovered lining its surface.

APPLICATION OF COLD IN CHOLERA,

PARTICULARLY AS EMPLOYED IN BERLIN.

To the Editor of the Medical Gazette.

42, Mortimer-Street, Cavendish-Square.

SIR,

DURING the early part of last September I had the opportunity of witnessing the re-appearance and progress of the Asiatic cholera in the town of Berlin, and also the treatment of the disease by the free use of cold water, both externally and internally. My friend, Professor John Casper, M.D. has employed this treatment with great success, both upon the former incursion of the cholera, and also during this second attack. The same accomplished physician has very recently published a small work "On the Treatment of the Asiatic Cholera by the Application of Cold," (Die Behandlung der Asiatischen Cholera durch Anwendung der Kälte), of which I beg to offer a few extracts, accompanied by some observations of my own, drawn from an experience of about twenty cases treated in that manner under my own observation, in the hospital at Berlin.

Before I describe this plan of treatment, it is necessary to premise, that Professor Casper "regards the Asiatic cholera as a paralysis of the functions of the skin, and that the cause which produces the disease, primarily attacks the cutaneous surface, paralyses it, and lastly kills it; and that all other pathognomonical symptoms must be regarded as consequences of this first seizure."

The Professor then proceeds at considerable length to support this theory; and I have endeavoured to arrange the different parts of his argument according as he attaches more or less importance to them.

1. "The skin in all cholera patients, from the simplest degrees of diarrhœa cholerica up to the most frightful forms of the disease, has lost its *extensibility* and *contractility*."

If the skin of cholera patients be pinched up into a wrinkle or fold, particularly about the sides of the neck and the lower part of the abdomen, it feels between the fingers of a peculiar flabby, doughy, death-like consistence; and the plait or fold, which has been thus made, does not, as in the healthy elastic skin, immediately subside, but on the contrary, if left to itself, it remains elevated for some time, and only very gradually sinks down again. This state of the skin is more or less apparent according to the severity of the case; and "in well marked forms of the disease, one may give to a large fold of the skin, particularly about the lower part of the abdomen, any direction at pleasure—as curved like an S—and the skin will sometimes remain in this form for nearly half an hour.

"This pasty, sluggish condition of the skin, is the only constant, never-failing symptom of this disease, whilst each of many other peculiar symptoms are wanting in particular cases. On this account," the Professor adds, "I would particularly call the attention of my professional brethren to this symptom, first pointed out by myself, because it is truly pathognomic, and in doubtful cases confirms the diagnosis, which is here so especially important."

2. The diminished temperature of the skin, from a state of coolness to that of icy coldness.

3. The shrivelled fingers and toes; also, 4. the collapsed countenance and sunken eyes, all indicate a want of turgescence in the vessels of the skin, and diminished vitality of that organ. "According to my observations the temperature of the skin is not indicated so low by the thermometer as it appears to the touch; still it is always remarkably less than in its normal state."

The most powerful stimulants applied to the skin scarcely produce any effect.

"Frictions, which were so much advocated, only cause a transient redness of the surface, and if employed in excess, destroy the cuticle beneath; and on this account are the cause, at a later stage of the disease, when the vitality of the skin returns, of severe and tedious sores. The same remark may be made of the application of mustard poultices and common blisters."

After reasoning on the injurious after effects of such remedies, the Professor communicates the following interesting facts, to the correctness of which I can add my testimony.

"Being fully convinced of the slight re-action produced by all hitherto recommended stimulants of the skin, I very soon arrived at the employment of a more powerful one, which I have now applied more than an hundred times, and

the operation of which is therefore well known to me.

"I lay upon the region of the stomach a piece of linen, previously dipped in spirits of wine, which I then ignite by the application of a common lighted match. I allow the flame to burn about five seconds, and then extinguish it by covering it with the bed-clothes. It is impossible," says Dr. Casper, "to apply an easier, more simple, and efficient stimulus to the skin. This cautery always produces re-action; sometimes indeed, in the very worst cases, the patient only moans, or makes an attempt to extinguish the flame with the hand; at other times, however, the patient screams out loudly, and in many cases complains for a short time after of a burning sensation; and this is always a favourable sign.

"Even this powerful stimulant, in cases of cholera, does not raise a blister; at most there is a redness around the edges of the linen; but I can also affirm, that in many cases there remains not the slightest trace as to where this application was made."

I must confess, that when I first saw this remedy employed in the hospitals of Berlin, it astonished and alarmed me, and I supposed the effects upon the skin would be very severe. The result was quite contrary to my expectations. The effect was exactly that described by Dr. Casper; and in some cases I could find no trace of this convenient cautery. It is, however, principally employed in the after stages of cholera, particularly in the typhoid state accompanied with coma, and then of course the effects of the burning spirit are proportionably greater as the surface has regained its vitality.

6thly. The bloodless state of the skin, and of the vessels of the extremities, indicates nothing else than the prostration of the vital powers of the surface of the body.

"It is well known to physicians of cholera hospitals, that leeches and cupping-glasses obtain very little blood In the asphyctic form of the disease (stage of collapse), the blood-vessels of the extremities are more or less empty, and on this account venesection in such cases is an unnecessary trouble to the patient.

"I have already communicated to the medical public (in the Berliner Cholera Zeitung), that my talented friend, Professor Dieffenbach, has exposed and opened the brachial artery in some of my patients, and that it was found *completely empty*. In other cases a mere thin clot of blood was found in it; and only once, in the hospital of a colleague, was a stream of blood found in the axillary artery."

7thly. The after-diseases of cholera may also be regarded as explanatory of this view of the nature of the disease. "Of such secondary diseases, the most common are serous effusions and exanthematous eruptions. These do not occur as distinct diseases, but generally commence towards the termination of cholera, immediately after the congestive or typhoid stage. Amongst these I have observed eruptions resembling varicella, roseola, urticaria, and the common furunculus, and likewise a general scaling off of the skin. Œdematous legs, and fatal effusions into the chest and abdomen, take place at a later stage."

8thly. "The low, hoarse, and often entirely lost voice of the cholera patient, one of the most common symptoms, agrees with the above views; for the same sympathy between the skin and the organs of voice is often shewn in the hoarseness of catarrh attending a severe cold."

9thly. "In a like manner the want of secretion of urine might be attributed to the sympathy between the skin and kidneys, were not this symptom more easily explained as a consequence of the frequent and copious stools, which must draw off the fluids from the kidneys."

10thly. The mucous membrane of the small intestines, in persons who die from cholera, is always found of a reddish colour, and the vessels more or less injected. Analogous phenomena are observed after death from extensive burns, from confluent small-pox, from pemphigus, and, in short, in all cases where a large extent of the skin is so much injured that it is incapable of performing its important functions. "All these above mentioned phenomena seem to agree better with this view of the disease than with former theories; so that I must repeat, that I consider the extinction of the vitality of the cutaneous surface as the essence or nature of the cholera, and as the principal cause of the subsequent phenomena.

"When it is necessary to excite—to raise, the prostrate vital powers, and that an extreme state of depression is

present, I believe that there are no means more powerful, none more quickly efficient, and, at the same time, none more simple and natural in accomplishing this point, than the application of cold itself; it excites and rouses the person by the mere act of shivering; it animates the surface, and relieves the internal organs; because nature, repulsing that which is inimical to herself, makes an effort against the cold."

It is said that the Persians stripped their cholera patients naked, and poured cold water over them; but of their practice we have not sufficient information to draw any conclusions from it. "Also in St. Petersburgh, in Riga, and Königsberg, cold affusions over the cholera patients were employed in some cases; but this application of cold was not satisfactory, because internal stimulants were made use of at the same time; and from the experience that, in spite of the cold affusions so many died of the cholera, this plan was not thoroughly prosecuted. On this account I hope, through the publication of the following method, to encourage my colleagues to a complete and persevering use of cold, and, at the same time, to abstain as much as possible from all remedies which are exciting or heating, and only to make use of such as are very gentle in their operation.

"*Treatment.*—The cholera patient is to be lifted from the bed, and placed in a large bathing tub. When the skin is dry and wrinkled, the bathing tub should be quite empty; but when the skin is softer, and moderately perspiring, or when it is covered with a clammy sweat, some luke-warm water (92° Fah.) should first be poured into the tub, so that the patient may sit up to the hips in water, and the upper part of the body remain quite uncovered. Three or four bowls or pitchers of water should then be poured successively over the head, back, and chest. The assistant should recede a few paces from the end of the bath, and then dash a bowl of water over the patient's chest and stomach. The affusion of cold water should be performed very quickly, and then the patient should be lifted into bed, and wrapped up in a dry blanket. In the very worst cases no re-action follows this operation; in less desperate cases the patients sigh and groan; and in the slighter they attempt to get away. The slight re-action after the first of these baths will, in the greater number of cases, astonish those who have never applied the remedy. In favourable cases the re-action is more manifest upon the future use of the bath; and the greater or less degree of resistance is very important in determining the favourable or unfavourable prognosis on the case. These baths should be repeated every three or four hours, according to the severity of the case.

In addition to this, I order cloths wrung out of cold water to be applied to the head, and, in bad cases, also over the chest and abdomen. I regard this application of wet cloths as a principal remedial agent in this plan of treatment, because, on account of the frequent changing, they are continually new stimulants.

"If the patients complain of chilliness, I always consider it a favourable symptom. The attendants have little trouble with these wet cloths at first; later, however, the cloths become more quickly warm and dry, on account of the vitality returning to the surface, and then they must be more frequently changed. All fear of cold is here, I can most boldly assert, quite misplaced, and is only a "clinging*" to the recollections of the heating plan of treatment.

"In less urgent cases I have not applied the cold wet cloths to the body, but am so partial to the cold applications to the head, that I never omit them even in the slighter cases. I have found that they are always agreeable, and that nothing so effectually prevents the typhoid stage as these cold applications to the head.

"At the same time I envelop the feet in hot flannels, or cloths wrung out of hot water.

"This, and only this, method warms the cholera patient; but it accomplishes it gradually, and the warmth may almost be said to be seen coming from the internal parts to the surface of the body, and thus requiring a more frequent application of the cold fomentations.

"With this treatment is combined the internal use of cold water, cold table-beer, or lemonade. At the commencement of the epidemic I followed the generally recommended plan, and would not allow my patients cold drinks.

* "Anklang" in the original.

Since I have permitted my patients cold drinks, I have never had any cause to regret it.

"Lastly, when the employment of purging clysters is indicated, I even apply cold in this form, by injecting equal parts of cold water and vinegar, with the addition of a table spoonful of common salt."

I should here observe, that Professor Casper is far from employing cold applications in all cases of cholera, or always to the same extent. When there is simple diarrhœa cholerica, he treats it upon ordinary principles, and only resorts to the above-described application in the approaching or confirmed stages of collapse.

According to Dr. Casper's experience, bloodletting is only indicated at the commencement of cholera, when the diarrhœa cholerica is present, and also upon the development of the stage of re-action.

The same remarks hold good with respect to the application of leeches, which in the stage of re-action must be repeatedly applied to the head. At the same time cold cloths should be continued to the head, and the further use of the bath discontinued; and calomel gr. ij. c. pulv. rhei. gr. v. may be given every one or two hours.

"After an experience in 400 cases," adds Professor Casper, "I am convinced that, in the severest forms of cholera asphystica, all internal medicines are useless, and therefore I give none; but I make use of the application of cold in its fullest extent, with hot applications to the feet. If this succeeds in restoring vitality to the surface of the body, this form of the disease is reduced to one less severe, which, according to circumstances, I treat with bloodletting, calomel and rhubarb, and the liq. ammoniæ acet."

This little treatise is accompanied by some clinical reports of cholera cases; but I fear this paper has already transgressed its proper length. Neither Professor Casper nor myself pretend to offer the external and internal use of cold water as specifics in the treatment of cholera; we merely assert that this is the most powerful means of bringing on a stage of re-action and a return of vitality to the surface.

I must add, that I have seen patients in the worst stage of collapse, livid, cold, and pulseless, removed from their beds to the bath like living corpses. After the application of the cold affusions, as above described, I have watched them for half an hour as they lay wrapped up in the blanket. After the lapse of ten minutes or a quarter of an hour, I have observed the cholera physiognomy gradually disappear, and the natural countenance return; the livid colour of the surface change into a more healthy hue; the icy coldness succeeded by a moderate but genial warmth; and the before pulseless arteries at the wrist offer a sensible expansion under the forefinger of an anxious by-stander.

I am, sir,
Your obedient servant,
GEORGE BURROWS, M.D.
Physician to the Cholera Establishment of St. Bartholomew's Hospital.

VALUE OF PREVENTIVE MEASURES — CHELTENHAM EXEMPT FROM CHOLERA.

Board of Health,
Cheltenham, Nov. 3, 1832.

SIR,

I BEG leave to acquaint you, for the information of the Lords of his Majesty's Privy Council, that the malignant cholera has now entirely subsided every where in this neighbourhood. The Board of Health of this town have in consequence felt it their duty to make the following report to their Lordships:—

The town of Cheltenham having been surrounded in all directions for several months by this disease, without its occurrence in it, the Board beg leave to express their belief, that, under divine Providence, this exemption from its ravages has been owing to the great care that has been taken in the removal of every description of nuisance, as far as was practicable; together with the airy and healthy situation of the town generally.

In the discharge of the duties entrusted to them, their first care was to prevent, as far as it was possible, all vagrants, trampers, and other suspicious travellers, entering the town from infected districts. Constables were placed, with proper assistants, to guard the principal avenues, by which means near two thousand persons of the above description, (and who could not give a good

account of themselves,) were, after being relieved, either sent back from whence they came, or conducted circuitously on their way. This important duty was effected at an expense comparatively insignificant.

In the removal of nuisances generally, the Board are bound in justice to state that their endeavours have been assisted with the greatest cheerfulness, not only by the parochial and other authorities connected with the town, but by individuals generally.

Inspectors, who were members of the Board, minutely examined every quarter of the town, and even every individual house, where filth and nuisances were likely to exist; and, as far as was practicable, the Board had them removed.

In many of the crowded streets, the Board discovered numerous nuisances connected with want of proper ventilation:—yards common to several houses; pools of stagnant and filthy waste water, which had no outlet; with privies and pig-sties of the most filthy description; which of themselves, from the exhalations constantly arising from them, contaminated the air, and became a fertile source of fever, and other contagious diseases. These, in many instances, have been entirely removed, and in all greatly abated. In fulfilling this duty, all stagnant water was removed, and the places purified with lime; and wherever the nature of the ground admitted of it, drains and water courses were made, to prevent a recurrence of similar future mischief. More than seven hundred houses have been thoroughly cleansed inside and out, and lime-washed in the most effectual manner. All accumulations of dung, dust, rubbish, or other impurities, have been removed, in doing which the Board received every assistance from the gratuitous loan of carts, &c. belonging to the constituted authorities and individuals; as well as by being liberally assisted with pecuniary and other aid, by the different neighbourhoods which required cleansing. By these means, the expenses of the Board were in many instances much diminished.

In the formation of culverts—a measure of great importance from their permanent advantages,—the Board have the satisfaction of stating, that in different parts of the town, and where they were most urgently wanted, they have been constructed to the length altogether of nine hundred and eighty-seven feet, and generally above three feet in heighth. This is independent of others, which have been made entirely by individuals at their own expense, at the recommendation of the Board. In this great work, the Board have been aided in so spirited a manner by public bodies, and individuals who have property contiguous to them, that the whole expense to the Board upon this head has not exceeded twenty-six pounds.

It may be of importance here to mention, that in a populous neighbourhood, and where one of the longest culverts and most wanted was constructed, the typhus fever had for a long time been fatally prevalent. This disease has since entirely subsided in that district; furnishing an instructive example of the great importance of an efficient drainage to the public health.

Similar beneficial results have been found from a minute attention to the state of the lower description of lodging houses, where vagrants and trampers congregate together in great numbers. These have been minutely inspected and visited, often two or three times a day; the bedding and furniture attended to; and in every instance, they have been thoroughly cleansed and lime-washed: while their management, it is hoped, is improved.

The first duty of the Board after its formation was the establishment of a Cholera Hospital. An eligible house was taken, fitted up with beds, and every necessary for the reception of patients. A nurse was provided, and except an expenditure for coals, there has been no other on this head since, except the rent, which is thirty-five pounds a year.

I have the honour to be, sir,
Your most obedient, humble servant,
THOMAS NEWELL, M.D.
Secretary to the Board.

To the Clerk of the Council,
Council Office, Whitehall.

ANALYSES OF SIX REPORTS ON CHOLERA.

Transmitted to us by the Central Board of Health.

DRS. BAIRD and MACRORIE, MESSRS. M'CULLOCH and NIGHTINGALE (Liverpool, Oct. 27), in charge of the wards

of the Fever Hospital, appropriated to cholera. Admitted, 210 cases; died, 117; recovered, 93: of the fatal cases, 48 almost immediately after admission. Have bled in all cases when bilious diarrhœa did not yield to opiates, astringents, &c., following this up with calomel, ʒj. and opium, gr. iss., a wineglass of brandy in water, having a drachm of carbonate of soda added to it. Afterwards calomel and opium in small doses, for a few hours, followed by castor-oil, with or without laudanum. Many cases so treated have run into consecutive fever, but this has been mild; at least rarely fatal. Collapse has very seldom followed where system became affected by the mercury. Vomiting and spasm at stomach always relieved by cupping and sinapisms. In second stage, bleeding adopted, if vital powers not greatly depressed. An enema of a pint of warm water, thirty drops tinct. opii, and a grain of sulphate of copper, generally arrested the serous discharges. A scruple or half drachm dose of calomel, with gr. i. to iij. of opium, followed up by minute doses of the above, or by hyd. c. creta and laudanum, every five minutes. Soda water, tea, cold water, &c. for drink. When vomiting urgent, with severe cramps, and dejections ceased, croton oil an "invaluable remedy." When stools have assumed a sanguineous appearance (a very fatal symptom), turpentine, with æther and laudanum, has completely changed their appearance, rendering them healthy; although the patients have sunk immediately after.

In third stage, bleeding at the commencement of the epidemic seemed to do good; latterly it has done harm. Have nothing to say in favour of any of the remedies so much vaunted in this stage. Towards its termination, the epidemic assumed a more malignant character.

"When we say that the cases recently admitted have put on a more malignant type than in the earlier period of the epidemic, it may be necessary to explain in what respects the difference consists. In the first place, there is an almost entire absence of pains and cramps at the stomach and extremities; secondly, purging and vomiting are neither so profuse nor severe; thirdly, there is less blueness, or discoloration of any kind, of the skin; and, fourthly, there is a great development of heat over the whole surface of the body: yet, with these symptoms, apparently so favourable to the success of remedial measures, we regret to say, that, let the practice adopted have been what it may, we have, in the great majority of these cases, been baffled in our efforts to arrest the progress of the disease."

Dr. Bournes, Coventry (Oct. 29.)—In premonitory stage, calomel, followed by castor oil; then rhubarb and ginger, or soda with a few drops of laudanum, every five or six hours. If pain in stomach, bowels, &c. a mustard emetic was generally exhibited first. In more advanced stage, however, an "antistimulant and antinarcotic" plan; giving "little" opium, and "less" brandy. Approves of the saline powders and abundance of cold water being allowed, and had been in the habit of using it before he read Dr. H. Shute's paper in the Medical Gazette. The Doctor enters upon some theoretical views, into which we regret that our space is not ample enough for us to follow him.

Mr. Humphreys, of Bonhill (Oct. 23).—Has had the medical charge of cholera cases in the above parish. In the form of bilious diarrhœa, as well as in all other stages of the disease, thinks highly of venesection, followed by a powder consisting of pulv. ipecac. comp. grs. v. given at intervals of two hours, until the purging ceases; afterwards, the following: calomel, gr. x.; jalap, gr. v.; rhei, gr. v. M.

In rice-water evacuations, after bleeding, a pill containing calomel, gr. iij. camphor, gr. iij., and opii, gr. ss. every half hour, until purging ceased, with a little hot brandy and water. Has found a draught containing sulphuric æther and laudanum useful, when given every half hour or oftener. Friction with turpentine; tin cases filled with hot water; mustard cataplasms to abdomen, calves of legs, soles of feet, and to chest. Clysters of starch, with tinct. opii. If local congestion, leeches, cupping-glasses, with blisters, and mercurial purgatives.

In collapse, tries to abstract blood. Relies principally on calomel and opium, gr. v. to x. of the former, and gr. ss. to ij. of the latter, at intervals of half an hour to two hours. When heat is restored, and vomiting and

purging abated, gives calomel, grains x., jalap, gr x., rhei, gr. v. Has sometimes given croton oil, in doses of from one to three drops: in two instances it gave great relief, by causing a large discharge of flatus. Attributes his success in this period of the disease to his constant endeavours to cut short the fever, by giving quinine at an early stage. When stomach continues irritable, has found large clysters "very valuable." Remainder of treatment same as in second stage. No cases or numbers given.

Mr. Symonds, Surgeon to Oxford Medical Dispensary, (Oct. 30.)—In first stage has found an emetic of ipecacuanha, followed by half grain or grain doses of opium and ipecacuanha, made up into pills with aromatic mixture, and repeated every three or four hours, "the most available remedies." When diarrhœa is very urgent, gives in addition to the above, after every liquid evacuation, two spoonsful of chalk mixture, with tincture of catechu, and six or eight drops of laudanum. When the diarrhœa takes on a chronic form, has found the sulphate of copper and opium, in half grain or grain doses, made up into pills, with aromatic powder, "not a little serviceable."

In the second stage has found the disease yield without difficulty to calomel in grain doses, combined with about a sixth of a grain of opium, repeated every half hour or hour until the alvine excretions have assumed their natural appearance. Gives with every dose of the calomel saline effervescing draughts.

In third stage gives calomel in larger doses—a scruple to half a drachm. Considers bleeding, in the second and third stages, of great power, but requiring nice discrimination in its employment. Cold water *ad libitum*. When nausea continues, approves of a blister to the epigastric region, and hydrocyanic acid in drop doses, in plain water. Disapproves of opium and stimuli.

Mr. Prouse, Bristol, (Sept. 1832.)—Disapproves of bleeding in the early stage. Has been very cautious in the administration of purgatives. Astringents freely used in slight cases with very great success. Considers that alum, chalk, catechu, and opium, have amply repaid the confidence placed in them. Carbonates of soda, &c. uniformly efficacious in the removal of acidity from the alimentary canal. Has used stimulants in large quantities in the worst cases, carefully regulated by the indications in each particular case. Gave nitrate of potass in 20 or 30 grain doses, and in general with the desired effect. Has treated upwards of 150 cases, of which number 3 only proved fatal.

Dr. Hardy, of Doncaster, has favoured us, under date 27th October, with two cases of cholera of the most formidable description, successfully treated by means of full doses of calomel (gr. v.) every quarter of an hour. The Doctor thinks favourably of the mustard emetic. He concludes with the following judicious observations:—"Having been in attendance on more than 100 cases of this disease, there is no fact of which I am more convinced than that the patient's best security is in the very frequent visits of the medical attendant, who is thereby enabled to prevent his own intentions from being defeated, either by the whim or dislike of the patient to the means prescribed, or by the caprice of the nurse or friends of the sick."

[The preceding paper is addressed to the Gazette, not to the Central Board.]

ANALYSES & NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'Alembert.

Observations on the General Principles, and on the Particular Nature and Treatment, of various Species of Inflammation. By J. H. James, Surgeon to the Exeter Hospital, &c.

This is the best manual on the subject of inflammation which we at present have in the English language. John Hunter's great work neither is, nor ever was, fit for the perusal of the student, from the complicated and unskilful construction of the language; and Dr. Thomson's volume is both out of print, and nearly as much out of date, as that of his great predecessor. It is deeply to be regretted, that the learned professor in the northern school has not found leisure to bring his work, in new edition, down to the knowledge of the present period. The work itself is so good, that the pro-

fession has felt disappointed to see it suffered to fall into the back ground, when, by a little activity, it might have been retained in the first rank. It is satisfactory, however, to find that Mr. James is resolved to extend his "Observations" to all that is passing around. On a stem originally good, he has engrafted the fruits of other men's labours, and added to their value by the culture of his own mind. The chief additions are to be found in the accounts of diffuse inflammation of the cellular texture, as well as in that of fascia, and of blood-vessels, both arteries and veins —on all of which subjects, but particularly the last, much information has been presented to the public through the medium of this journal. The style of the author is perspicuous and good, the views are practical and judicious, and the volume altogether extremely well "got up."

The Substance of the Official Medical Reports upon the Epidemic called Cholera, which prevailed among the Poor at Dantzick, between the end of May and the first part of December, 1831. By JOHN HAMETT, M.D. &c.

WE have already published the chief results of Dr. Hamett's labours—indeed, the earliest extracts from them appeared in this journal (Dec. 24, 1831, page 441, also p. 473, also p. 532.) As, therefore, we devoted many pages to these papers in a former volume, it is unnecessary for us to do more at present than announce their publication in a complete and extended form, by the author himself; at the same time stating our opinion, that they constitute as complete a history of the epidemic in one particular place, as can well be conceived.

Dr. Hamett is a most zealous non-contagionist, and more than insinuates that he was unfairly dealt with on that account after the dissolution of the first Board of Health. This is a question between him and the parties to whom he refers. For ourselves, though adopting opinions at variance with the author's, he must do us the justice to acknowledge, that we took the earliest opportunity which was afforded us of making known his views—while we confidently appeal to our readers whether we have not invariably given as free admission to the communications on the one side as on the other. We allude to the subject, because we perceive that a vapouring blockhead has been recently stating this and other circumstances connected with the Gazette to be—just the reverse of the facts.

The Anatomy of the Horse, embracing the Structure of the Foot. By WILLIAM PERCIVALL, M.R.C.S. &c.

THIS volume contains a complete account of the anatomy of the horse. It is furnished with an excellent index, rendering it easy of reference. The plan of the work is good, and we have no doubt, from Mr. Percivall's reputation, that it is correctly executed. The description of the foot, in particular, is very full and distinct. To the veterinary surgeon, desirous of being completely master of his art, the work cannot fail to be acceptable.

MEDICAL GAZETTE.

Saturday, November 10, 1832.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."
CICERO.

ASSOCIATIONS FOR THE PROMOTION OF SCIENCE.

WE take up our pen to acquit ourselves of a task too long left unperformed. It was with feelings of no ordinary interest that, within the last half-year, we witnessed the regularly organised proceedings of one, and the organization of another, admirable association, expressly instituted for the advancement of knowledge, and the promotion of friendly and familiar intercourse among the learned; but our incessant engagement with one ephemeral topic or other, pressing at the moment, though comparatively, perhaps, less important, left us but little leisure and less space, to pay that tribute of approbation which, however we felt it due, we were sensible did not need immediate payment. We ac-

cordingly procrastinated longer than we could have wished, and, of course, in coming forward at the eleventh hour, are sensible that we lack that gracefulness and influence of recommendation to which at an earlier and more convenient season we should have undoubtedly been entitled. Not that even now we have any thing new to offer, in stating our views of what we have looked upon for some time with unmingled satisfaction, but in inditing the few observations which follow, we feel that we shall have tendered in some sort an earnest of our good will, and a cheerful homage of that which we are aware would have been better worth acceptance had it been presented sooner.

Both the associations of which we speak have the interests of medicine at heart—the one collaterally, the other directly; both have indisputable claims upon the patronage and support of the profession. It is true that, at the Oxford meeting of the British Association, which took place in June last, the transactions which had medicine for their object were of a hurried character, and not very well managed; but that cannot again occur; the fault was not unnoticed at the time, and measures to prevent its recurrence will not be wanting in future. In place of throwing the medical sciences into the section of natural history, it is understood that physiology will henceforth have a distinct section allotted to itself, and that in other respects many necessary and desirable arrangements will be effected. It is only surprising to us how so much has been already done in the way of order, the last being but the second meeting of this grand national institution.

The proceedings of the other association have yet to be seen: as yet they have been but preparatory; but the objects of the society being strictly professional, or, as we have said, directly medical, less difficulty can be experienced in arriving at perfect harmony of organization. May we not be excused if we give a more distinct account of the nature and objects of this society? Its existence and express purpose cannot be too extensively made known throughout Great Britain; and we premise that, in contributing our services towards this end, we need do little more than avail ourselves of the excellent address of Dr. Hastings, delivered upon the occasion of the first meeting of the association, held at Worcester in July last.

In presence of an assemblage of some of the most distinguished practitioners of the provinces, Dr. Hastings being called upon for his statement of the plan of the society—already in some measure explained in the circular by which the meeting was convened—that gentleman came forward. He congratulated the assembly on the promptitude with which they had obeyed the call, and announced the large number of applications which he had had besides from all quarters of the country—from eminent cultivators of medical science, who were anxious to be enrolled among the members of the proposed association. To the editors of the Midland Medical and Surgical Reporter was the credit of its suggestion due; they had, after four years' experience in conducting that work, convinced themselves that provincial labourers in the field of medical science are neither few nor valueless, and hence, that the enterprise which they recommended was not only feasible, but would be certainly crowned with success They proposed to associate the provincial medical practitioners of England in a comprehensive co-operating institution, which, by bringing the energies of many minds to bear on one object—the advancement and the dignity of the art—would place medicine on that sure and honourable foot-

ing in this country, which there is no good reason why it should not attain. Dr. Hastings then read from the prospectus, drawn up by the committee, the following list of objects to which the attention of the new association should be directed:—

1. The collection of useful information, whether speculative or practical, through original essays, or reports of provincial hospitals, infirmaries, or dispensaries, or of private practice.

2. Increase of knowledge of the medical topography of England, through statistical, meteorological, geological, and botanical inquiries

3. Investigation of the modifications of endemic and epidemic diseases in different situations, and at various periods, so as to trace, so far as the present imperfect state of the art will permit, their connexions with peculiarities of soil or climate, or with the localities, habits, and occupations of the people.

4. Advancement of medico-legal science, through succinct reports, of whatever cases may occur in provincial courts of judicature.

5. Maintenance of the honour and respectability of the profession generally, in the provinces, by promoting friendly intercourse and free communication of its members; and by establishing among them the harmony and good feeling which ought ever to characterize a liberal profession.

The means by which these objects are to be carried into effect are, first, the holding an annual meeting of the members at some one of the provincial towns (it will be Bristol in 1833,) changing the place of meeting each year; and secondly, in addition to thus securing the advantages of friendly intercourse, by devoting the time of each meeting to such special business as shall be calculated to promote the cause of medical science. It is proposed for the furtherance of the latter object, that it shall be the allotted duty of one of the members, to give a history of the progress of medicine during the year expired, *or* to pronounce an oration on some such subject, *or* to read a biographical memoir of some eminent cultivator of medical science who may have resided in the provinces. We do not see why all three should not be regularly performed by three competent individuals, and thus three valuable contributions be bespoken for the volume in which the annual transactions shall be recorded. Dr. Conolly's suggestion is also very important, that a certain number of members shall be appointed each year, whose duty it shall be to report on the state of medicine in foreign countries. Thus the state of the science in France, Germany, Italy, and America, would become familiar to the members, and much interesting information could not fail to be elicited. "In this respect," adds Dr. Hastings, "the British Association may be imitated by us with great advantage. They have appointed committees of their body to select the points in each science which most call for inquiry, and endeavour to engage competent persons to investigate them; and they attend particularly to the important object of obtaining reports, in which confidence may be placed, on the recent progress, the actual state, and the deficiencies of every department of science." It is understood, in consequence, that in the Provincial Association a certain number of members will be appointed annually to report at each meeting the progress of the distinct branches of medical science during the preceding year.

We will not follow Dr. Hastings in his able summary of the various departments of medicine, in which he shews that investigations laborious and minute are still wanted: but we fully concur with him in most of his positions, and at some future period may bestow further attention upon them. The result of the meeting has been, as we suppose most of our readers are already aware, that the Association is now regularly organized, with its President, Secreta-

ries, and Council. It is very gratifying to observe the list of members which we have before us: it includes a surprisingly large number of distinguished practitioners—all resident in the provinces, and who have all pressed forward eagerly and at once to testify their desire of mutual co-operation.

It is impossible to contemplate the formation of a great professional body like this, without anguring from it the most important consequences. Union, which, under ordinary circumstances, is productive of the most striking results, becomes an engine of incalculable value, when, as in the present circumstances, it is directed to the attainment of an end that is both great and good. What—even if nothing more were to be expected—what can be compared in value to the friendly feeling, and good understanding, which must inevitably grow out of this periodical intercourse between educated men, leagued together with so noble a design? "Men," says an eloquent writer, "not only accumulate power by union, but gain warmth and earnestness. The heart is kindled. An electric communication is established between those who are brought nigh and bound to each other in common labours." And if such be the case with mere masses of human beings, how are the chances of accumulated power increased when the mass consists of the educated and the refined? That the validity of so natural an inference should be questioned, appears to us to be so remarkably absurd that we cannot easily forget the comment of a leading journalist, when, in the course of the summer, he condescended to notice the congress of British science at Oxford. He argued, that because there were ample means of scientific intercourse through the press and the post-office, it was perfectly idle and superfluous for learned men to be congregating together for the mere purpose of *viva voce* announcements of their labours. He left out of the question altogether the main purpose of their assembling; and, with singular obliquity of intellect, or obtuseness of natural feeling, would not, or could not, appreciate the value of friendly and familiar intercourse. "Iron sharpeneth iron"—can be a proverb of no truth or application to such a man; though perhaps it might be otherwise if that metal could sharpen *lead*.

MEDICAL APPLICATION OF MATERNAL SORROW.

M. Double—whose name must be familiar to our readers as that of an eminent physician in Paris—had lately occasion to read a memoir to the Academy of Sciences, in which he mentions the following circumstance as having first directed his attention to the sounds of the heart. Many years ago, when he was taking leave of his mother, she laid his head upon her bosom and wept in an agony of maternal grief at parting with him: but her philosophic son was otherwise employed the while. He was struck with the distinct manner in which he heard the beating of her heart and the convulsive sobs of her breathing—he listened to every sigh as illustrating the principles of acoustics—and hence he assures us the origin of the mode of examining into diseases of the chest by auscultation, now so generally adopted. M. Double evidently thought the anecdote redounded to his credit; but we fear he will look in vain for any compliment on the score of feeling—truly his *sang froid* was indeed *cold blooded*.

MILITARY HOSPITAL, ALGIERS.

CLINICAL OBSERVATIONS ON WOUNDS FROM FIRE-ARMS.

By M. Baudens,
Surgeon-Major, and Professor in the Algerine Hospital.

WOUNDS OF THE FACE.

There are few lesions which at first sight appear to be so serious as those of the face,

especially when inflicted by wounds from fire-arms; yet they are seldom dangerous. In almost every instance cases which have looked very alarming have got well without difficulty—the surgeon principally taking care to prevent the spread of inflammation to the interior of the head. But care must be also taken of the lips of the wound, when union by the first intention is aimed at; for if they be not refreshed and connected by a few sutures, the cicatrix will be furrowed and jagged in place of being linear and invisible. After fire-arms this caution is particularly requisite, for gangrene cannot be united to gangrene. I shall select a few remarkable cases.

WOUNDS OF THE EYES.

Lesion of the Orbital Arch—Emphysema of the Eye-lid—Cure, but with loss of sight and memory.

M. D., a captain of the 30th regiment, in the sortie from Medeah was struck by a ball at the inner third of the orbital arch, on the right side. The projectile shattered the external plate of the frontal sinus, and remained so fixed in the internal as to compress the anterior lobe of the brain. I removed it with some difficulty, dressed the wound, and had the patient, in a state of coma, carried to Algiers. I did not see him till three days after. There was then fever present, which I combatted with antiphlogistics. I found also that there was a fistulous communication formed between the frontal sinus and the anterior ethmoidal cells, attended with emphysema of the eye-lid. That the air passed through this communication was evident when the patient sneezed or blew his nose. I recommended him to avoid as much as possible doing either, and with the help of nitrate of silver and a compress got rid of the fistula, as well as the emphysema of the lid. But the eye itself, though apparently not at all altered in its structure, was totally deprived of the power of vision, which I attribute to injury of the frontal nerve of the fifth pair, the communications of this branch with the nasal twig of the same nerve, and the connexions of the latter to the ciliary nerves of the ophthalmic ganglion. The memory is so much impaired that the patient loses all recollection of his acts. Things which interest him now, in twenty-four hours are completely obliterated from his mind. All that happened to him previous to the accident he remembers perfectly. His power of expression, so far as relates to calling things by their right names, is also much impaired. What support does this afford to the opinions of Gall and his disciples?

Lesion of the Crystalline—Extraction—Cure.

Mustapha, a Turkish cannonier, aged 60, a robust and vigorous man, was struck, at the explosion of the Emperor's fort, by a small round stone about the bigness of a large pin's head, which came from below upwards, and after tearing through the transparent cornea of the right eye lodged in the crystalline. It was on the third day after his accident that I saw him. He was then suffering under intense ophthalmia; the globe of the eye was voluminous; exophthalmia was commencing; and there was a purulent discharge proceeding from the lens, in the centre of which the stone was easily perceived. The wound in the cornea was cicatrized. I performed the operation for cataract by extraction, when scarcely was the cornea divided when the crystalline, compressed by the humours of the eye, was forcibly expelled, together with the stone and the aqueous humour. I bled the patient several times, bandaged up the organ with closed lids so as completely to exclude the light, and in about six weeks found that the organ had recovered its power—not perfectly, however, owing to the Turk's impracticableness. I have preserved the stone carefully.

Singular lodgment of a Ball in the Orbit without any very visible external injury.

At the descent of Mount Acoza, Z. a private of the 28th regiment, feeling himself struck about the external angle of the right eye, hastened to the ambulance. The eyelids were by no means ecchymosed. The conjunctiva towards the external angle of the globe was red, a little injected, but not torn. The inferior eyelid slightly swollen. Not having time to examine the parts more attentively, and taking the patient's word for it, that he must have merely been hit with a small stone or branch of a tree, I dressed the eye simply, and put compresses on it steeped in cold water. I found the man afterwards in the hospital at Algiers. M. Molinard had discovered behind the lower eyelid a roundish body, receding on the slightest pressure: it was doubtless a ball, which should be removed immediately, in order to check the progress of acute ophthalmia setting in momentarily. He made a transverse incision through the lid: but the impossibility of fixing the foreign body rendered all attempts vain at extracting it in this way. On the following day, he bethought himself of making the patient roll back the eyeball, while he drew forward the lid, so that he was enabled to get a spatula behind the foreign body, and to remove it by leverage. Nothing more was to be done but to combat the ophthalmia, which was soon got under.

WOUNDS OF THE NOSE.

Wounds of this nature, especially if at-

tended with loss of substance, singularly mar the harmony of the visage. All the resources of our art, then, ought to be put in practice to prevent such deformity.

Loss of substance of the Lobes of the Nose—Rhinoplastic Operation—Cure.

A soldier was shot across the base of the nose, and nearly deprived of the whole of that part. The bare nostrils exhibited a frightful appearance: but little of the septum remained; and the bones of the nose were shaken, but not shattered. I pared the edges of the wound, and, after the example of M. Larrey, detached portions of the integuments on each side over the canine fossæ; by means of which, with the aid of a few sutures, I masked the bony skeleton of the nose, and supplied the place of fibro-cartilage by allowance of integument for the base, and stuffing slightly with charpie the cavity of the artificial nostrils. In short, I succeeded in giving the organ the desired form, and especially prevented flattening at the base by the application of wooden pincers. In six weeks all was well.

Perforation of the Right Nostril, and Stoppage of the Ball in the corresponding cavity.

When we were at Mount Atlas, B. a soldier, who was attending me in the ambulance, received a shot in the middle of the right nostril. The ball was of the cylindrical kind. It made a large opening for itself, but remained free in the nasal fossa, without touching the septum in any remarkable manner.

Perforation of the floor of the Nasal Cavities and of the Tongue by a Ball—Cure.

A corporal, who was at the bottom of a ravine, was struck with a ball, coming downwards, which divided into two portions the lobe of the nose, broke part of the cartilage and the vomer, passed through the floor, pierced the tongue and soft parts situated under the median raphé between the os hyoides and the lower jaw. Another soldier received a similar wound, except that the ball stopped on the tongue, and scarcely did it any injury. In both cases, after removing the bony splinters, the lobe of the nose was replaced by sutures, and cold fomentations were applied to the parts. The first case experienced an intense glossitis, which required a deep scarification of the tongue. In other respects, the cure was complete in twenty days. There remains, of course, in both patients an anormal communication between the mouth and nose, which will require in one of them the constant application of an obturator.

WOUNDS OF THE CHEEK.

Lesion of the Maxillary Sinus and the Parotid Gland—Cure.

A soldier of the 28th regiment was struck, below the zygomatic apophysis of the left side, with a ball, which came out at the opposite side, in front of the *pavillon* of the external ear. The projectile crossed the maxillary sinus, the bony structure of the face, and the parotid gland. The escape of air along with a quantity of bloody mucus, left no doubt of the lesion of the maxillary sinus, while the parotid gland, much bruised, was covered with an eschar. Having carefully removed the splinters of bone, I pared the edges of the wounds made by the entry and exit of the ball, and closed them by sutures. A slight compression, managed carefully, over the first aperture, and a strict injunction to the patient not to make any effort in blowing his nose, sufficed to stop the air-passage. There was not much danger of a subcutaneous emphysema, as the integuments were so strongly adherent to the parts more deeply seated, and as the cellular tissue was here so little permeable. But in thus closing the two orifices, in order to prevent the formation of fistulous openings, one aerial and the other salivary, had I not reason to fear for the consequences of stopping up the natural issues of the purulent discharge which generally attends gun-shot wounds on the removal or fall of the eschars? My experience did not give me reason to entertain any such apprehension; for I was well acquainted with the energy of absorption observable in wounds of the face;—and, besides, did not the nasal fossæ offer an easy exit for the flow of the purulent matter? With the aid of a severe regimen and general bleedings, the cure was complete: after a month's treatment, the linear and scarcely visible cicatrices adhered to the subjacent parts. The aerial fistula never reappeared—the salivary did not exist for a moment. The patient was one of those soldiers who were twice wounded in the defiles of Mount Atlas. He received a ball in the arm, the wound from which got well without accidents.

Singular Wound by a Spent Ball.

An officer of the 30th regiment, who went, with his cigar in his mouth and sword in hand, to cover the retreat of the army in the descent of Mount Atlas, had his mouth completely full of tobacco-smoke, which even kept the dental arches asunder, when he was struck on the right cheek by a spent ball, which entered and lodged in the oral cavity without any other lesion than the perforation of the soft parts which it met in its route. The officer spat out the tobacco-smoke and the bullet together. There still remains a slight scar on the cheek.

DR. ELLIOTSON.

On Thursday afternoon (the 8th,) when the second sheet of this journal had been made up, we received a letter from Dr. Elliotson in reply to our last leader, in which we pointed out some inaccuracies into which he had fallen, respecting the Medical Schools of England. The letter contains questions requiring categorical answers, as to numbers, &c. which we are unwilling to venture upon off-hand, for the satisfaction of a gentleman in such a state of prodigious excitement as the learned Professor appears to be, and by whom the slightest inaccuracy would obviously be magnified into a heinous offence. We therefore postpone it till next week, pledging ourselves both to insert the letter, and to answer every point which it contains. If Dr. Elliotson had really wished it to be inserted in this week's Gazette along with the information which he professes to seek, he ought to have sent it sooner,—and he knows this: nevertheless, we find that it has been in time for the *Lancet*. It is admirably managed of the Doctor, thus to keep back his letter till too late for us (though it is dated the 6th), and meantime get it into the Lancet, which appears before us,—we must presume, of course, without any intimation to that journal that it was forthcoming; indeed the Doctor knows well that if he had sent a letter abusing the Gazette even at the eleventh hour, his patron would gladly have inserted it,—aye, though it had been necessary to cancel the first impression.

On the wrapper of the present No. will also be found an advertisement from Dr. Elliotson, intimating that he is not answerable for his Lectures as published in the *Medical Gazette*. The Doctor will find that we anticipated him in a note appended to his Lecture in the first sheet, and which was printed off before his communication was received. Dr. Elliotson is evidently quite prepared to find the Lectures inaccurate, and states that he has spent hours upon their correction. Those who know as much of the Doctor, and his compositions, as we do, will readily believe him: the fact is, he corrects and recorrects the merest trifles, apparently striving to give to elaborate and studied Lectures the appearance of being unpremeditated. The reader will find a fair specimen of his errata in our last No. wherein two commas, in different parts of the Lecture, are directed to be struck out, and the limb of a parenthesis (God save the mark!) transposed. We have, in truth, been most distressingly hampered by these puerilities, and shall explain to our readers next week the inconsistencies of which *we* apparently have been guilty towards them, regarding those same Lectures, and by which it will be seen that we could not much longer have submitted to the inconvenience and injury caused to our journal by complying with Dr. Elliotson's request, that he might be allowed to see the proof-sheets,—even though we had not been so presumptuous as to question the infallibility of his views in our last leader. We ventured to criticize Dr. Elliotson's opinions just as we should have done those of any other man,—*hinc illæ lachrymæ*.

To prove, however, that Dr. Elliotson has no ground for anticipating inaccuracies, we have to state, first, that his Lectures have been taken down by the same first-rate short-hand writer, whose reports of Mr. Lawrence's Lectures were so much admired for their correctness; secondly, that we have had Dr. Elliotson's Course taken down by the same expert hand during two successive seasons,—so that we have the extraordinary advantage of two copies to compare, in the event of meeting with any questionable passage. The Doctor's proofs have been preserved, and are still in the hands of the printer, in order that the exact nature of the corrections may be proved, if the Doctor compels us to do it. Lastly, we appeal from Dr. Elliotson condemning by anticipation, and in a state of excitement, to Dr. Elliotson in his calmer moments—we challenge him to point out any instances of inaccuracy.

LECTURES

ON THE

THEORY AND PRACTICE OF MEDICINE;

Delivered at the London University,

By Dr. Elliotson.

CUTANEOUS DISEASES.

VESICULÆ.

We now, gentlemen, enter upon the consideration of those inflammatory diseases of the skin which are characterized by the secretion of fluid under the cuticle. I shall begin by speaking of those which are characterized by the secretion of a thin watery fluid; and among these, of such as exhibit very minute collections, so that the first description applies to those which are termed *vesiculæ*. If the liquid be not water but pus, the diseases are called *pustulæ*; if the secretion be water, and the collections are large, the affections are called *bullæ*. Vesiculæ and bullæ merely differ in point of size. The contents therefore of a vesicle are serous; they are also called *limpid*, but limpid is an indefinite word, and it is therefore better to say serous.

Definition of the terms Vesicle and Scab.—A vesicle is defined by Dr. Willan to be a small orbicular elevation of the cuticle, containing lymph (we had better say serum), sometimes clear, transparent, colourless, but often opaque, whitish, or coloured. The serum may be quite clear, or it may be rather opaque, or purple; and such an eruption as this may be succeeded either by a scurf or by a scab. If the fluid be absorbed, and the cuticle which is detached rub off by degrees in minute portions, you have scurf; if, on the other hand, the fluid be not absorbed, but the cuticle is ruptured, as the fluid exudes you then have a scab formed by the drying of the fluid. A scab may be formed either by such serum, or by pus; of course, therefore, in this disease you may have a scab. A scab is defined by Dr. Willan to be a hard substance formed of fluid discharged from ulceration. A scab may be formed, therefore, either of serous fluid, or by the concretion of pus.

Miliaria.

Now the first disease among those which are characterized by a watery secretion in a minute collection, and of which I shall speak as being the most minute—as having the most minute vesicles—is the miliary eruption; it is called in Latin, *miliaria*. In this disease the vesicles are exceedingly minute, and exceedingly numerous, about the size of millet seeds; whence their name. There is a slight inflammation of the skin, and a slight rash; sometimes a little more, and then the disease is called *red* miliary eruption. If there be scarcely any, or what there is disappears, and there be only white vesicles, then it is called *white* miliary eruption. Some imagine that the red is neither more nor less than scarlet fever. Formerly the diagnosis was so imperfect that many cases of miliary fever were called scarlet fever; however, if there be much inflammation the skin will be red; if not, it will look white, from the number of these little vesicles.

Now these miliary eruptions are very frequently nothing more than attendants upon other diseases; they will come on at an uncertain period of various cutaneous diseases. In measles and in scarlet fever you continually see a little miliary eruption. I have frequently seen it on the hands in the case of acute rheumatism. These eruptions are most abundant on the breast, neck, and back; on the face and extremities they are less copious, and they will appear and disappear in uncertain order.

Symptoms.—If the disease be very copious

indeed, the eruption is immediately preceded by an unusual degree of languor and faintness, and by a profuse perspiration, which perhaps accompanies it the whole of its course, and which is sour to the smell, or smells like rotten straw. There is sometimes a sense of heat pricking and tingling in the skin before the eruption comes out, and even during it. The vesicles at first are exceedingly small, and filled with transparent lymph; but in about thirty hours the lymph will become more or less opaque and milky. The tongue may be affected; it may be dark and red at the edges, and the papillæ may be elongated. There may be aphthæ of the mouth and fauces.

Duration.—The duration of the disease is very uncertain; it is said to last from seven to ten days, or longer; but crop after crop may come out, and protract the case perhaps six or seven weeks.

Causes.—Now this disease is supposed by Bateman to be nothing more than the effect of bad treatment. It was very common formerly when lying-in women were kept in a heated room, when a number of blankets were placed upon them, thick curtains were drawn around the bed, and a fire was kept blazing in the apartment. Under all this it would have been strange if they had not sweated and had a miliary eruption of the skin. It is supposed that there never was a specific disease of this kind, but that it was the result of over-excitement of the body when there was more or less feverishness. Now there can be no doubt, I think, that there is such a specific disease as miliary fever, besides the miliary eruption which may be produced by stimulating a person improperly by heat. Formerly in this country, at different times, there was a disease called *sweating sickness*, which was characterized by these very symptoms; and this disease now prevails from time to time in some parts of France, as in Languedoc, and in Normandy. The disease has frequently prevailed in those places, not sporadically, but as an epidemic. These are moist places, and the disease is there thought to be—as old writers in this country declared it was—contagious. The fluid from a vesicle has been inoculated without success; but in the places I have mentioned people declare there is no doubt of its being contagious. It affects adults, and particularly women. It is said to prevail only between 43 and 59 degrees, north latitude.

Symptoms.—When it comes on in the epidemic form, it may, like most other diseases, be either mild or severe, so that it is divided into benign and malignant. The miliaria benigna is preceded by lassitude, frequently by pain over the eyes, and loss of appetite; but persons sometimes go to bed well, they wake in a profuse sweat, very soon vesicles appear, and they sweat on till they die, or the symptoms cease. Now and then before the eruption comes on, they complain, as people do in this country, of a sense of heat along the skin; and the sweatings are so profuse that the patient is actually steaming. In the violent form of the disease all the symptoms are intense, but the stomach is found to be particularly affected; what is called *gastro-enteritis*, an inflammation of the mucous membrane of the stomach and intestines, takes place. The sweats are very fœtid, and the patient smells exactly like rotten straw. The eruption generally comes out on the second or third day, and continues from two or three days to two or three weeks. There may be merely scurf afterwards, the contents of the vesicles being absorbed; or there may be an oozing from the vesication, and extensive desquamation may ensue: there may be violent headache, with giddiness and delirium. Such is the disease as it prevails in many parts of France. Several persons in Paris deny that there is any such disease, exactly as other people will sometimes deny things that they do not happen to see themselves.

Treatment.—The treatment of this disease, when it occurs as we see it from the effect of hot regimen, or a violent inflammatory complaint, consists in simply keeping the patient cool, and the whole will then subside. But abroad, when the disease prevails epidemically—when they have what is called the sweating sickness—then it is frequently necessary to take away blood, to give a patient fresh air, and, I should think, to sponge him well. But sometimes it is necessary to take away blood, and pay attention to the inflammatory state of the stomach and intestines—to take especial care not to give any thing that will irritate those parts—to give neither emetics nor purgatives. I should presume that other cases might occur, in which it was necessary to support the patient well.

The appearance of the eruption as we sometimes see it at the back of the hand in rheumatism, is very well represented in this plate (exhibiting one). You perceive that there is scarcely any inflammation. It is a thing of common occurrence, and the disease is easily recognised, in consequence of the extreme minuteness of the vesicles.

Herpes.

The next disease of this description is one of very common occurrence, but as far as I know, is without any danger whatever. It is called *herpes*.

Symptoms, &c.—Herpes is a vesicular disease, characterized by a great degree of inflammation at the base of the vesicles.

You may distinguish it from some other vesicular diseases, by the great degree of inflammation with which it is attended. It is a disease on which you will be continually consulted. Patients are very much frightened, and fancy they have some terrible disease coming; but you may easily quiet their fears, and indeed, for the most part, very little treatment is required. In most of its forms it is an acute affection; it begins, perhaps, with general feverishness, and a great degree of smarting and tingling of the skin; the skin looks red, and clusters of vesicles then appear; it generally lasts from eight or ten days to a fortnight. There is not a large number of vesicles diffused over different parts, but they occur in clusters, and cluster after cluster will appear. Those eruptions which you see coming on suddenly upon the chin, for example, are of this description. At first the contents may be clear, but they soon become opaque and yellow. The scabby mouths of children are nothing more than herpes. Now and then it will occur around the whole body. The patient shall be seized with a violent pricking, tingling, and smarting, and then vesicles are seen which form a cluster; and this will go on, cluster after cluster being formed, till a belt is made. In common language this is called *shingles*, but in medical language it is called *H. zoster*. Now and then the patient is a little indisposed at first; he has a little head-ache, and a little feverishness; but as often as not there is nothing at all. The disease, when it occurs in separate clusters, is called *H. phlyctænodes*; but when it extends round the body, it is *H. zoster*. That is the only difference in the two forms of the disease. In the plate you see there is a great degree of redness, a great degree of inflammation, and the vesicles here are larger than in the former disease; then again, if you look at that form which runs round the body, you see a high degree of redness. It can make no difference as to the nature of the affection, whether it occur in clusters or mere patches. There is at first smarting and tingling in both, and when this is all over there is great itching.

Treatment. — There is not the least danger in this disease, and the patient would do well if you gave him nothing. In this species of the affection, however, I believe it is a very good plan to cut the patient off from a little of his diet—to give him a gentle dose of physic—and one of the best applications to the part is oxyd. zinci. It is well not to apply grease—it irritates the part very much; but if you powder it with zinc, the fluid is generally absorbed, and you find the disease go away. You may thus lessen the smarting and the irritation, and lessen the duration of the disease: it would go away of its own accord, but you may mitigate it, and give considerable comfort to the patient.

Herpes Præputialis and Labialis. — This disease frequently appears in a very local manner—for instance, about the prepuce of the male; also on the pudendæ of women little vesicles will sometimes appear, which are herpes. They occur, too, about the lips and angles of the mouth, and sometimes they occur to a great extent over the mouth, and children, from picking them, raise a scab, and thereby induce a sore which lasts for a considerable time. If it occur on the prepuce, it is called *H. præputialis*; but if it take place on the lip, it then receives the name *H. labialis*.

Treatment. — Moderate antiphlogistic treatment, purging, the application of cold water, and some moderate astringent powder to suck up the discharge, is the best mode that can be adopted.

On the prepuce it is frequently mistaken for a venereal affection, and patients often go to medical men in a great fright.

Herpes Circinatus.—Sometimes the disease will be so arranged that you have a circular form of the patches, with the vesicles only on the circumference, and then it is called *H. circinatus*. It is merely a number of vesicles spreading on the outward boundary. This is represented here (shewing a plate). You see that it is all the same disease, and all the forms are characterized by a degree of redness. The great use of knowing the disease is, that you may not mistake it for a serious affection—that you may be able to give a good prognosis. The patches heal in the centre, and are commonly round; and hence it is called, by the common people, *ring-worm*.

Treatment.—The same treatment is applicable to every variety of this disease.

Herpes Iris. — There is one curious form of the disease which I have not seen above two or three times, where you have all the colours of the rainbow; and for that reason it is called *H. iris*. It occurs in circular patches, and each patch is of rather a different hue. It is generally seen on the back of the hands, and it occurred there in the cases that came under my notice. You will find it well described in Dr. Bateman's work. He says, "The central vesicle is of a yellowish-white colour; the first ring surrounding it is of a dark or brownish red; the second is nearly of the same colour as the centre; and the third, which is narrower than the rest, is of a dark colour; the fourth and outer ring, or areola, does not appear until the seventh, eighth, or ninth day, and is of a light red hue, which is gradually lost in the ordinary colour of the skin. The iris has been observed only in young peo-

ple, and was not connected with any constitutional disorder; nor could it be traced to any assignable cause." In fact, it is only inflammation of various hues. When speaking of inflammation in general, I said that it assumed different hues; a remark which is illustrated by the appearance of this affection. It is a very pretty sort of disease. There is no difference in its cause from the others, and no difference in its treatment. Sometimes we can discover no cause for this affection; but it will come on after some little error in diet. There are concentric circles, so that there may be a succession of these inflammations. Each of these forms of herpes may last a long time.

Eczema.

The next disease to which I will direct your attention is very much like herpes, so far as it is a vesicular eruption, but it differs from it in having little or no inflammation. This disease is called *eczema*. The decided difference between the two affections is, that herpes has a great degree of inflammation, and eczema none. You will frequently see an eruption of vesicles on the skin, without any inflammation at all; but they are larger than milaria, therefore they are not milaria, but eczema; and if there be inflammation attending them, you call it herpes. That is all the difference. You will very frequently see this on the neck or hands in summer. The eruption may last only two days, or it may last a considerable time.

Causes.—Any irritation of the skin may produce it; intense solar rays may give rise to it, and stimulating acrid substances will have the same effect.

Eczema Rubrum. — The disease, however, is sometimes very severe, extends over the whole body, and proves fatal. Perhaps we should hardly say it was the same disease; however it is so called by Willan. It is chiefly induced by mercury. Every now and then, when persons have taken mercury, they have been seized with great heat of the skin—with feverishness—a number of vesicles have appeared larger than the miliary; they have spread all over the body; the cuticle has come off; fluid has exuded; and the irritation been so great as to make the patient quite wretched. At the same time the mucous membrane has become affected, and there is almost always cough. This, however, is not all: I have seen more or less disease of the throat; frequently vomiting and purging; the mucous membrane running from the fauces down into the abdomen having also been affected.

Treatment.—In this severe form of the disease, which generally arises from some peculiar susceptibility of the constitution to mercury, it is necessary of course to leave off that medicine. It is well to give the patient the utmost supply of fresh air, to open the windows and doors, and ventilate the room as much as possible. The smell from the discharge is exceedingly disagreeable, and you find it necessary to apply something to absorb it; nothing answers better than zinc or calamine powder. The latter is exceedingly mild, and never produces irritation; so that you may have the patient well sprinkled with it. You also find it necessary to support the strength; to give nutritious broths, plenty of milk, and frequently porter, and even wine. There is extreme debility of body induced, and I have seen several die from it. Inflammation will come on, and you find a difficulty between supporting the strength on the one hand and subduing the local inflammation on the other; so that you have to give, not wine or beer, but good broths, and trust on the other hand to the depleting effect of leeches. The case is one which it is very unpleasant to treat; for after giving the patient the utmost support you can—tranquillizing his system by opium, and anxiously doing every thing you can—you will find that, after the lapse perhaps of six weeks, he will die; and it is not to be wondered at, when you consider the extent of skin which is in a diseased condition.

It is not always mercury which produces this disease, but by far the most violent form is that induced by mercury. All the cases that I have seen arose from that source. Other cases will occur, in which mercury has nothing to do with it.

Eczema Impetiginodes. — This affection is sometimes attended by the formation of a puriform serum. The disease runs into a pustular form, and is then likely to be chronic, and may last a considerable time. You see that the divisions of the disease are more or less arbitrary; for here we have a species of eczema which might, with equal propriety, be called impetigo, and therefore it is termed *E. impetiginodes*. This is represented here (exhibiting a plate), from which you perceive that there is scarcely any inflammation, compared with the intense redness of the other, and sometimes none at all.

Treatment.—In this local form of the disease occuring acutely, there is no need of any thing but just to give the patient a dose of physic that will do him no harm.

Respecting that form of the disease which becomes chronic and runs into a pustular affection, it really is so nearly allied to pustular diseases, that it will save confusion if I speak of it when I speak of impetigo. Every now and then you see a patient with vesicles in one part

and pustules in another; and therefore I think it better to speak of it under impetigo. If you choose, you may call it impetigo eczematodes, just as we have eczema impetiginodes.

Scabies.

Symptoms.—Another disease, gentlemen, which is seen more frequently in vesicles than not, is itch. It is spoken of by Willan and Bateman as a pustular disease, and it sometimes is so; but generally it is vesicular. Every body knows it by the watery heads, and therefore it may come under the head of vesicles. This is a contagious affection. The two last diseases of which I have spoken (eczema and herpes) are not contagious; but the itch is very much so. It is, however, contagious in the limited sense of that word; it cannot be communicated by the atmosphere. You may go as near to a patient labouring under itch as you please, provided you neither touch him nor handle him, without the least fear of imbibing the affection. But the itch is not so easily caught by contact as you might imagine. I have frequently touched people—taken them by the hand or wrist, not knowing that they laboured under the itch—without catching it. I once caught the affection, but then I was a little boy, and obtained it from the nursery maid. By washing my hands after touching them, I never caught it from patients. It is only by remaining close for some time, by sleeping with a person, or using something that they have touched for some time, that there is any chance of catching it. It is more commonly caught by sleeping with a person labouring under it, than by any other means. It is common for working men who come to London, and sleep in beds where the sheets have not been changed, to catch the disease. It is very common also among children who sleep together. More frequently than not, you find the disease caught by persons sleeping with one who has the disease, or sleeping in a bed in which some one labouring under it has slept before.

The itch is called in medical language *scabies*, and it occurs chiefly about the wrists, the roots of the thumbs, between the fingers, the ancles, and between the toes; but if it be any where, you are almost sure to see it about the thumb. It occurs, too, on the front of the body, on the chest, and in the axilla. I do not recollect having seen it in the face. These are all curious circumstances, and the reason of them I cannot tell; but it is far more frequently seen at the roots of the thumbs than any where else, then at the wrist, next between the fingers, at the ankles, between the roots of the toes, and next on the front of the chest. The disease is attended by an incessant itching. A Scotch king is alledged to have said, that no subject deserved to have it, on account of the great pleasure that was derived from scratching the affected parts.

I do not know how long the disease may last; it appears never to wear itself out.

It is attended with no danger whatever, except to young children. I have seen it excite such great feverishness in them, that if they had not been cured, it is possible that derangement of the alimentary canal or of the head might have been induced. If the patient scratch himself the vesicles are ruptured; they then dry, and get dirty, so that you have black heads. A little blood probably exudes; but between the dirt drying with the fluid, and a little blood oozing, you have small black heads. In children you may often be mistaken as to this disease; for the irritation is such, that superficial inflammation to some extent occurs. Besides this, between and around the vesicles there is frequently common inflammation of the skin, and it will cause desquamation of the cuticle, so that the appearance of the disease is much disguised. The intense itching, too, in infants, makes them rub their legs against each other, and that occasions the disease to be recognized with difficulty; but if you will look at the roots of the thumbs, you will see the vesicular form of the disease, and ascertain its nature.

Species.—If the eruption be of a watery character, the disease is called *S. lymphatica*; if it be very rank, resembling pimples, it is called *S. papuliformis*. These distinctions are not very important: it is of importance, however, to know that the disease is sometimes characterized by pustules—large, full, flat-looking pustules, resembling any thing but the little vesicles which you see in other cases. This is called in common language *pocky itch*: the common people know the disease well. In refined medical language it is called *S. purulenta*. This is a species of the disease often mistaken, from its being so unlike the common form of the affection. It occurs between the fingers and at the back of the hands and wrist, where you will see large pustules of that description called *phlyzacious*, attended with an inflamed base, and containing a thick yellow matter. When you have once seen the disease, you will have no difficulty in recognizing it again. It is said that this disease is sometimes caught from brutes which have the mange. When there is great inflammation, you will have suppuration necessarily induced. Even when you have the affection in this severe form, you will generally find that in other parts of the body the vesicles are very small. It is only where there is great irritation that this pocky form of the

disease occurs. You will recollect the general rule I laid down, that if you look all over the body, you will see the true form of the disease in some part or other.

I believe I mentioned, when speaking of fever, that it is very common after fever for itch to take place. I have frequently seen this occurrence, but whether it came on spontaneously, or contagion had been applied before, I cannot tell; it is, however, by no means uncommon for persons after fever to have the itch. The lymphatic form is that which generally occurs in such cases, a representation of which is contained in this plate (shewing it). For the most part you do not have the disease a thousandth part so severe as this. Some have imagined that this disease arose from a small insect, but that is only a part of the doctrine, that all contagious diseases depend upon animalculæ. Some deny that there is any insect; some declare that they have picked an insect out, and seen it through a microscope; but others declare that they never could do so.

Though this is not a dangerous disease, yet it is a very troublesome one, and is held in great abhorrence. If you tell parents that their child has got the itch, they hold up their hands as if it had got the plague.

Treatment.—I need scarcely say that the great remedy for this disease is sulphur—but why, no one can tell. I do not believe that it has any effect when given internally. When I have employed it externally, I never found the cure accelerated by its internal exhibition. It may be employed in the form of vapour, or by means of baths, or inunction. In the latter form, it should be rubbed in night and morning; and if a person do that, he will soon get rid of the disease. Some employ sulphur baths. Some have impregnated water with sulphur, and say they have cured the disease in that way rapidly, and in a more pleasant manner than by rubbing in the ointment. It is said by some who have had great experience in the disease among the lower orders, that it is more readily cured by what is called *sulphur vivum* than by pure sulphur; if so, it is probably from the acrid matters which this contains. If there be no great inflammation of the skin, the sulphur produces more effect if you add hellebore, or some stimulating substance. If the sulph. vivum answer better than pure sulphur it is on this account.

Pompholyx.

The last disease which we have to consider among those which are characterised by vesication, is what is called *pompholyx*. Willan, and also Rayer, make a separate order of this disease, while really the only difference is, that in those of which we have been speaking the vesicles are very small, and here they are very large. I cannot myself see the reasonableness of making a distinct order of diseases, when the symptoms are precisely the same, and the only difference is a difference of size. One might as well call a tumor by one name if it be as big as a nut, and by another if it be as big as the head. However, if the vesicles be very large, they are called *bullæ*; and because sometimes there are large vesicles in erysipelas, Willan and Bateman have placed that disease in the order bullæ; but as there are frequently only small vesicles, and indeed vesicles do not appear essential to erysipelas, therefore I have considered it, as Rayer does, under the order of rashes.

When there is a very large elevation of the cuticle, a large collection of water, the disease is called pompholyx. It was imagined formerly that there was a particular fever attended by an eruption of large bullæ, and it was denominated pompholyx; but it is now doubted whether there is a distinct fever of this description. In common continued fever, and in other fevers well known, there may accidentally be a large bulla, just as in other cases there are vesicles not larger than a millet seed—miliary vesicles. However, this disease, which is characterised merely by large blebs of water upon the skin, is not very common, and yet one can hardly call it uncommon. I suppose I may have seen about twenty cases of the disease. In many instances it is really nothing more than large eczema, or large herpes;—a vesicle will appear on the skin, and instead of being small as it is in eczema, it is large, and sometimes there is an inflammation around it just like eczema, and sometimes it is a good deal like herpes; that is the whole history of the matter. Now and then you will have a vesicle on the skin of a person out of health, and if it be small, it is herpes or eczema; but if it be large, it is called pompholyx.

Species.—You find in Bateman three varieties of this affection: one *P. benignus*, there is no great harm in that; one *P. solitarius*, because there is only one; one *P. diutinus*, because it is chronic. It is almost a pity to make these names, for who would conceive that there was much difference between benignus and solitarius? If it be solitarius it is likely to be benignus, and one is at a loss to see why sometimes it should have one name, and sometimes another. It is well simply to recollect, that the disease may come on with only one vesicle, or there may be several; or it may last for a short time only, or for a long time. It is very properly called diutinus;

but we might as well call many other inflammations by the same term, for many last a long time. I do not know why the term chronic should not be employed. You will recollect, then, that large vesicles on the skin, occurring as an idiopathic affection, is called pompholyx. Sometimes there are only one of these, and sometimes a succession of them, and persons will have them month after month. I have seen all these forms of the disease. A patient in the hospital for some other complaint, all at once, without any reason, has had a great bleb on his foot, and you have nothing to do but prick it and away it goes. There is no treatment necessary.

But P. diutinus is a very obstinate sort of complaint, and I never saw any thing do good in it. I have seen it occur myself under two forms; the one in a worn-out constitution, where bleb after bleb appeared on the skin, which cracked and oozed like a sore; and then, when the body was one mass of these, the health gave way and the patient died. In the other cases which I have seen, it came on in regular succession. I recollect the case of a woman who, once a month, had some large bullæ out on her face; they were attended with considerable smarting; the fluid which oozed from them produced inflammation wherever it went; it then dried up, and the cuticle healed.

Treatment.—I need not say that that form of the disease which occurs in a worn-out constitution requires to be treated by soothing measures. You must exhibit opium and moderate astringents, sprinkle calamine to suck up the discharge, and support the patient well by means of wine, bark, and good nourishment. In other cases, where there is no debility, one would attempt to treat the patient on antiphlogistic principles. I did so in the case of the woman where the disease came out once a month, but the success was very limited; the irritation certainly was diminished, but the eruption came out again. By looking out for local disease and attempting to cure it, applying the warm bath, and if any phlogistic state of the system occurred, taking away blood, we should be doing what reason dictated; but more than that I cannot say.

Before I proceed farther, I had better show you those large bullæ which are called pompholyx (exhibiting a plate). You see how large they are; but I have seen some much larger than these. Sometimes they are not attended with any inflammation around them; but, in other cases, there is a very sharp kind of inflammation, producing smarting, tingling, and a burning sensation. Then, when they break, you have an excoriated surface, and a scab is formed of the fluid and the cuticle together. All at once a person will have one of these on his face or head, or both, and be much frightened. Here there must be something more than an inflammatory state, because I have treated them with antiphlogistic measures, and have failed entirely.

ON SOME SUBJECTS COLLATERAL TO CLINICAL MEDICINE.

A Lecture delivered at St. Bartholomew's Hospital, November 10, 1832.

By Dr. Latham.

Mode of taking Cases—Suggestions and Cautions in the reading of Books—Systematic, Nosological, Practical Books—The degree in which they are valuable to the Student—Division of practical Medical Literature into that which regards Works of Observation solely, and that which regards Works both of Observation and Research into Morbid Processes—The last properly called the Pathological, and especially recommended to the Student.

I have again called you together for the purpose of making a few remarks upon some things collateral to our proper business in the wards of the hospital. The student often asks me such questions as these—Would you recommend me to note cases down for myself in writing? What books should I read, or what studies should I pursue, in aid of my daily observation of disease? These are certainly very important questions, and I will now give you the best advice concerning them I am able.

I often see young men, at the very commencement of their attendance upon medical practice, taking cases; and when I do, I always dissuade them from doing so. At present it is quite impossible that they can do what they desire: they literally can not take a case. Their present business is to observe. They must learn to know the things themselves before they can put them down and set them in order for use and reference.

A twelvemonth is the shortest period during which any student will attend medical practice, and I will venture to give this general advice. During the first three or four months record nothing; use your observation to the utmost; be continually in the wards, looking at the sick and asking them questions; be inquisitive about the effects of medicines; be listening perpetually, with your bare ears or with the help of the stethoscope, to the chest, that you may become familiar with the sounds of healthy respiration and the healthy contractions of

the heart; and then try to use the same means for the detection of disease. Accustom yourselves to feel the pulse; the number of its beats is easily measured, but it has qualities which are referable only to the sensations of him who feels it, and you must educate your touch to the discrimination of them; for these qualities, much more than its mere number, serve to guide us in the detection of disease and the method of treating it. The tongue, too, must be often looked at, before you will be able to detect upon it the marks which are morbid. There are certain secretions too, the different morbid qualities of which you must learn by frequent examination: the expectoration, the urine—both have qualities upon which may depend the diagnosis of disease and the choice of remedies. I am not now making any orderly enumeration of symptoms, but merely instancing a few cardinal points with which habit must render you a little familiar and enable you to appreciate the information they are calculated to convey, before you can take cases for yourselves with any promise of advantage.

Let me also mention the physiognomy of disease. This can never be adequately described, and I urge you always to remark it and to dwell much on it; for some acute observers have drawn such secrets from the expression of the countenance, that it has been to them in the place of almost all other symptoms.

I would recommend, then, that for three or four months the student should allow his curiosity to range discursively among every variety of disease, familiarizing himself with the great signs which belong to all, before he binds down his mind to the rigid contemplation of particular cases. When I say discursively, I still mean diligently, and with an earnest purpose of improvement: and, in the course of three or four months thus employed, you will pick up much real knowledge, you hardly know how, but you will find it such as will stay by you.

And now you may begin to take cases: but take only a few at first, and be discriminate in your choice—let them be instances of well-marked acute disease; and, when you enlarge your number, I would advise you to employ yourselves upon several of the same denomination at the same time. Take three or four cases of dropsy, or of fever, or of rheumatism. Thus you will learn, by the benefit of comparison, what can be learnt in no other way. You will see shades of difference in the diseases themselves, arising from external circumstances or from the different constitutions of those who bear them, and a consequent variety in the modes of treatment required.

Take your cases in one of two ways. Either take them altogether independently for yourselves, or copy them out of the book kept by the clinical clerk, adding any particulars of observation or comment which may have occurred to your own minds during their progress. The last is the least laborious way, and I think the best, provided you make a point of never copying cases which you have not attentively watched during their whole course. At all events, you might trust to the clinical book for furnishing you their framework or leading facts, and their history; and thus leave yourselves more at leisure to note down your own remarks from day to day, as the cases proceeded.

If, in this employment, you make a good selection, and do your work carefully, you will, at the end of your hospital attendance, take away with you a little body of practical medicine founded on your own experience, which will be useful to you, very useful, as long as you live.

Do not let a suggestion which I am going to add seem trifling, or impertinent. I would wish to see the freest intercourse between pupils, with a view to mutual instruction. I would rather find two or three taking the same cases together, than one so employed alone. You have it in your power thus to give infinite help to each other. Of all modes of instruction, that is the most agreeable, and often the most valuable, where one a little senior, or a little more advanced in knowledge, communicates information to another not quite so forward. There are, besides, many little difficulties which no man can tell you better how to surmount than he who has just succeeded in surmounting them. At this day I continue to feel gratitude to two or three individuals a year or two senior to myself, whom I found at this hospital when I first became a student.

Then comes the important question, what books the student should read, and what studies he should pursue, simultaneously with his attendance in the wards of the hospital, in aid of the objects he has now view?

Now let me tell you, first of all, that there are some books which you should be very cautious how you read at the present period of your education.

Perhaps it may appear very strange to you, that while you are intent upon observing the symptoms of diseases and the effects of remedies, I should advise you to be very sparing in reference to books which treat expressly of such matters. You see the things themselves; then why learn them at second hand? I do not know that I have any objection to certain elementary books—"Vade Mecums," "Practical Manuals,"—provided they are short. Such

books are to the medical student what maps are to the traveller. They give a succinct summary account of the whole subject according to the last survey; they help him to explore the country; but no man can be said to know a country who has gone over it only on the map. The map may have given him his first general notion of it; but his more intimate acquaintance with it—that sagacity which enables him (if I may so say) to take the right turn in the dark—can only come from the habit of perpetually traversing it. Such are elementary books of practice to the student of physic. He wants them to tell him where he is, and just to give him a start; but he must never trust to them for any thing beyond this. The misfortune is, that these books are too often read, not to assist, but excuse the labour of practical observation. Many a young man has preferred to sit by his fire-side and read "Thomas's Practice of Physic," to a diligent attendance upon the sick in the wards of an hospital; and the consequence has been, that he has started into practice with Thomas under his arm and nothing else, and Thomas and he have been companions through life, and he has never been able to do without Thomas to his dying day; seeing and reading all things through Thomas's spectacles.

There are some books which are found in the hands of all students — books of nosology, and particularly Cullen's Nosology; which I am told they think it almost necessary to commit to memory. This they do respective to their examination. Now I do hope, since it is now prescribed to the student that he shall busy himself in learning disease *by actual observation* during one whole year — I do hope that he will be allowed the fullest, freest, and most unfettered exercise of his mind, to acquire knowledge *in the way prescribed;* that teachers and examiners will conspire to aid his progress *in that way*, and keep him from running out of it; and that, as he is told to learn physic in the wards of an hospital, he will *there* be taught it; and that, when he ultimately comes to be examined, he will be examined as one who has *there* been taught it, and has *there* learnt it, and no where else. If young men are to be examined nosologically, they must learn nosologically. They must commit to memory technical arrangements of disease; and the time required for this labour they must deduct from their hospital attendance. Nor is the loss of time the greatest evil: their minds are led astray from their proper object; for, while they are learning a nosology by heart, they are no more studying physic than if they were digging and delving in a field. It has often grieved me to see young men saunter about the hospital square, with a little book in their hands—grinding Cullen's Nosology, which they are sure to forget in a few months—instead of going from bed to bed, full of interest and alacrity, and gathering knowledge which would become their own, and remain with them as long as they live.

A more just way of examination upon practical medicine is this—first to ask the candidate what are the diseases which he has actually seen during the period of his hospital attendance, and then to make him give a strict account concerning them and their mode of treatment. Upon these terms *he* would always pass the best examination who had gone on acquiring knowledge in the way best suited for its use in after life, without thinking how he should be able to produce it in a technical form a few months hence.

No one should be examined beyond what he has seen, and he should be expressly asked what that is before he is examined. An attendance upon medical practice during a whole twelvemonth, in a large hospital like this, would bring him acquainted with an immense variety of diseases; so that there would be no fear of the examiner's interrogatories being cramped within too narrow a sphere.

What encouragement would it be to a zealous pursuit of practical medicine, if the student knew that this would be the form of examination to which he would be ultimately subjected! I am not without a hope that this will soon be the case.

But even if this were the case, it would, in my notion, still fall short of what is both desirable and attainable. I believe we have been all hitherto wrong; or, to speak more boldly still, I believe the best schools never yet were right, in the prescribed modes of imparting and acquiring, and ascertaining, the knowledge of practical medicine. The very examinations themselves should be conducted in the wards of the hospital. The presence of the patient is necessary at every step, for teaching, for learning, and, finally and most of all, for examining. Surely it is not possible to tell whether a man knows disease unless you see him in the very act of searching after it and finding it; or whether he can treat disease, unless you see him while he is applying his remedies to it.

But (it would be said) the arrangements of an hospital would not admit of all this. Nothing would be easier. This great hospital can provide for any thing which is manifestly conducive to the public good. I would only ask for a small ward containing half a dozen beds; and these beds should be occupied by half a dozen well-chosen cases, drafted from the rest of my patients.

This ward should be my clinical school, and into it none should be admitted but myself and half a dozen pupils. These I would have under examination for a month, and then the same number should succeed them; and so on, month after month, all the year round.

But how should I thus have them under examination for a month? By making them act before me, for a month together, the very part they will have to act, for good or for evil, as long as they live. They should have the cases under their own care and treatment, but strictly under my superintendance; for this superintendance would constitute the examination. They should question the patient before me, and apply whatever means they thought fit for the detection of his disease, and give their reasons for whatever notion they might form of it. Then they should prescribe before me, and make choice of their remedies, and give their reasons for whatever indications they thought fit to follow in the treatment. In short, every day they should give the same sort of little lectures as I am accustomed to give upon each patient as I go round the wards.

At the end of the month, I would give a certificate of competence to those whom I thought deserving of it.

This method, besides being the best possible test of the knowledge which a man had already acquired, would also be a lesson of instruction in the use of it. Such an examination, or rather such a practical exhibition of knowledge, in its use and exercise for a month together, would have none of the annoyance, either actual or prospective, which belongs to examinations as they now are. As this would be the most profitable, so it would be the most pleasurable part of the student's professional education. There would be none of the posing and puzzle of formal interrogatories, but, instead of them, there would be the ease and comfort of the most unreserved communion between pupil and teacher, upon the subjects most interesting to both.

After a student has gone through his prescribed course of education, and been examined, he is ready to practise as soon as any body will employ him; and I would ask any person of common sense to which of the two he would submit his body with the greater confidence—to him who had Vogel, Sauvages, Cullen, or any other nosologist, by heart, or to him who, having spent a twelvemonth in the diligent observation of a great variety of diseases in a large hospital, had brought his knowledge to the test of practice during a whole month under the eye of the physician?

In making these observations, I confess my desire that they may reach beyond those to whom I am immediately addressing them. All the years I have been an hospital physician, I have deplored the languid interest taken by students in medical practice. I wish, with all my heart, it were otherwise; and I will give all my diligence that it shall be: and let me hope to engage on my side those especially whose zeal in raising the standard of professional education cannot be doubted, and that they may aid me in making that department of instruction which belongs to me more easy, more popular, and more productive of good fruits.

I was led to make these observations in speaking of certain nosological books which students seem to be under some necessity of reading prospective to their examination. This is unfortunate; because I doubt whether, beyond this purpose, you will find them of any use.

There is another class of books, not systematic, yet purely practical; which professedly discuss the treatment of diseases and their nature and essence, entirely with reference to their cure. They are generally written upon some one particular disease, or upon several diseases of a like character. Some of them you will feel a great temptation to read.

Among this class are found the great treasures of medicine, and among the writers of them are found the great benefactors of the human race. The writer of a good practical book on medicine, who tells the world something which it did not know before—something of large application in fortifying or restoring the health, strength, and comfort, of man's body and mind; or who, if he tells nothing new, yet wisely sets in order what is already known, and gives it a better and more convenient adaptation to the same high purposes; such a writer, in all just estimate of things, is second, and second only, to the great expounders of moral and religious truth.

But, unhappily, among this same class of books is also found every thing that is wretched in the literature of our profession; and the bad practical works have a mighty predominance of quantity over the good.

In the shape of practical treatises our own age and country has bred, and is breeding, and the press is assisting at the birth of, the oddest and most worthless trash; and this often obtains a wide circulation, and a strange popularity.

While you are watching various diseases, you cannot help feeling a desire to know what they have said concerning them who have expressly written about them; and in your wish to read something, you are, without direction or warning, as likely to lay your hand upon a bad book as a good one:—Nay! more likely; for a bad book is generally a very easy book, having been composed by its

author with no labour of mind whatever; whereas a good book, though it be not necessarily a hard one, yet, since it contains important facts, duly arranged, and reasoned upon with care, must require from the reader some portion of the same attention and study to comprehend and profit by it as it required from the writer to compose it. A good book, at all events, is never a very easy book, and never suddenly popular.

What books of the practical kind you should read, I will tell you presently; what you should not read, I will tell you now.

Never read any book that bears internal marks of being addressed more to the public than to the profession. They are all bad, and many dishonest.

Mind that you are not betrayed to commit yourselves unwarily to books (especially of modern date) upon diet and digestion, upon the liver, and the stomach. Unfortunately, the public is well understood to have such a relish for reading upon these subjects (such a moral appetite for knowing what may peradventure give them a physical one) that new motives have been thus let in for medical authorship, which are not very creditable. There is a demand for books of the kind, and if they are executed with some plausibility, they have a certain sale, and a certain kind of reputation is gained by them. Any of you, who may feel himself a little sharp and clever, might write such a book to-morrow, with a tolerable chance of all its attendant advantages. There is not a medical publisher in this town who would not give you something handsome for a "bold bad" book upon the stomach.

But there are books upon practical medicine, written in our own times, much talked of, and containing much that is good, which, nevertheless, a student just beginning to observe for himself would do well to avoid, for they are sure to give an undue bias to his mind. Books, I mean, in which you find some strong predominant theory; as where numerous diseases, apparently different, are uniformly ascribed to some single cause, and an uniform practice recommended in conformity to the theory; where, for example, every sort of pain in whatever part, or every species of nervous complaint, is attributed to plenitude or emptiness of the blood-vessels, or to errors in the functions of the liver, or the stomach, or the duodenum, or the bowels generally; and bleeding or leeches, or mercury or purgative medicines given accordingly.

I do not mean to say that such books may not be read with profit; but they can only be so read when the reader is able to guard himself with the checks and reserves of his own experience. They have for the most part been written by men of talent; and, in attempting to shew that all, or nearly all, diseases are cured by the pursuit of one indication of treatment, while they fail of establishing the point they intend, they succeed in establishing something short of it. They often shew that the indication in question is just in many cases, and that it is one which deserves to be borne in mind in all.

The seat of fever is placed by one modern author, whom I greatly respect, in the head; and by another, in the abdomen. According to one, all febrile movements radiate from inflammation of the brain as their centre; according to the other, from inflammation of the mucous membrane of the bowels. The doctrine of both as a piece of philosophy, is untrue; but still both Dr. Clutterbuck and M. Broussais have deserved well of the profession, in so far as they have contributed to establish two paramount indications in the treatment of fevers—by shewing, that in numerous cases our success will entirely depend upon the undeviating steadiness with which we address our remedies to the head or the abdomen. Hereafter you may read these books, but not at present.

I think I can illustrate all I have to say by one great example. Recollect, I am cautioning the student, the medical student especially, against trusting his mind to the fascination of any tempting theory, before he has put it fairly upon its guard by much independent observation of his own.

The work of Mr. Abernethy upon "the Constitutional Origin of Local Diseases," has extraordinary merit and originality. The substance of the whole is this—that local diseases are rather symptoms of a disordered constitution than primary and independent in themselves; and that they are to be cured by remedies calculated to make a salutary impression on the general frame, not by topical dressings or any mere manipulations of surgery. All this is good, and entirely justified by experience.

Next, that this disordered state of the constitution either originates from, or is rigorously allied with, derangements of the stomach and bowels, and that it can only be reached by remedies which first exercise a curative influence upon these organs. Even thus far it is a beautiful theory, and I am not disposed to deny it a large share of truth.

Then come to be considered the real nature of these visceral derangements, of which little distinction is made, and the remedies proper for their cure, which lie in the small compass of a blue pill, or a compound calomel pill, at night, and a mixture of gentian and senna in the morning.

Practically the sum of all is this: that be the local disease what it may, the constitutional ailment what it may, and the derangement of the stomach and bowels what it may, this one method of treatment is at all times applicable.

What a tempting theory this is; and what a still more tempting practice! As soberly set down in print, the student can hardly help receiving them; for, being once faithfully received, what a world of tedious study and observation must they save him.

You, who never knew Mr. Abernethy, and have only read the doctrine which I have endeavoured to sketch, as it is carefully and beautifully developed in his book, have no notion what he made of it before his pupils in this room. A vein of it ran through every lecture that he gave. In his book it stands as a suggestion to surgeons, concerning the constitutional origin and treatment of local diseases; in his lectures it acquired an amplitude and extent which embraced every kind of disease incident to man.

You, who never knew Mr. Abernethy, have no conception of his powers as a lecturer. He so eloquently expounded some of the highest truths; he so nicely disentangled the perplexities of many abstruse subjects; he made that so easy which was before so difficult, that every man who heard him feels perhaps to this day, that, for some important portion of his knowledge, he is indebted to Mr. Abernethy. But he reserved all his enthusiasm for his peculiar doctrine; he so reasoned it, so acted it, and so dramatized it (those who have heard him will know what I mean); and then in his own droll way he so disparaged the more laborious searchers after truth, calling them contemptuously "the Doctors," and so disported himself with ridicule of every system but his own, that we accepted the doctrine in all its fulness. We should have been ashamed to do otherwise. We accepted it with acclamation, and voted ourselves by acclamation the profoundest of medical philosophers, at the easy rate of one half hour's instruction.

The great Lord Chatham, it is said, had such power of inspiring self-complacency into the minds of other men, that no one was ever a quarter of an hour in his company without believing that Lord Chatham was the first man in the world, and himself the second; and so it was with us poor pupils and Mr. Abernethy. We never left his lecture-room without thinking him the prince of pathologists, and ourselves only just one degree below him.

Now that an important practical doctrine had been unfolded, is most true; and that it had been carried to an unwarrantable extent, is most true also: but how far to accept it, and how far to reject it, were questions for the sober judgment of a matured experience.

Therefore I do say, that this great teacher, in so far as he taught an exclusive doctrine, and claimed for it an almost universal application, and won an acceptance for it by the fascinations which genius, and fancy, and eloquence can command—I do say, that this great teacher gave a hurtful bias to the mind of the student, and indisposed him to the indispensable task of observing for himself. For how is it possible that the mind, the youthful mind especially, can bind and buckle itself to the labour of getting possession of knowledge in the hardest possible way, by sifting every particular, and by patiently observing at the bed-side, when it believes itself already furnished with all the wisdom which such laborious and *jealous* processes can ever teach? Yes, observation of disease is not only a laborious but a *jealous* process; it allows nothing to pass but under the warrant of the most cautious reasoning, or of the senses themselves; for these are the natural sentinels of the truth.

Summarily then, I will venture to say, of all books which enter minutely into the practical examination of particular subjects, and those especially which open peculiar views, that it requires much personal experience to form a correct judgment of them, and to profit by them. While you are yet inexperienced in the subject-matter, you may be pleased with them as an argument, or a process of reasoning, and thus they are likely to make an undue impression upon your mind. But you will be at a loss about the simple conceptions, which are the pith and marrow of the whole. Under such and such conditions, and on such and such emergencies, says the writer, I reason thus; and this is my view of the case; and this is my practice. But to estimate the justness of his views, and the propriety of his practice, you must first be familiar with the conditions and emergencies he speaks of.

I fear that by this time you are beginning to fancy me possessed of some strange prejudice against books; for that, whether they be good or bad, I still find some reason for advising you not to read them.

Indeed, it is not so. In what I am now saying, I am only endeavouring to explain myself a little more at large concerning a subject upon which I have occasionally conversed with you in the wards, when (as often happens) some one has asked me what books he should read upon this or that disease, which has at the time been the subject of observation. In truth, I want to excuse you to yourselves from any misgivings you may have, that you are not doing all you might for your own informa-

tion, when you are *not* reading about every disease you see; for I am persuaded of nothing more certainly than this, that there is a previous necessity of disciplining our own mind by an independent course of observation, in order to fit it for any thing like profitable instruction by the teaching of other minds, or, indeed, to furnish us with any tolerable security against being deceived instead of being taught.

They only who are practically informed can read good books with profit, or bad books without injury.

But still the literature of our profession, in its direct bearing upon practice, is a matter of the highest concern to you all. It is true that you cannot make any great acquisitions in it at present, but you ought to begin even now; not by running from this writer to that for a scantling of knowledge concerning each particular disease as it presents itself, but by seeking an acquaintance with those great writers who hold the keys to the just knowledge of all diseases, and the just administration of all remedies. Simultaneously with the observation of cases in the wards of the hospital you must begin to learn pathology; and the study of pathology, and the observation of disease, begun together in this place, must never be separated in your minds as long as you live.

Hitherto I have spoken of books generally only, and as they may chance to fall in the way of the student; but now I would lead you to view a little more closely the character of medical literature in its bearing upon practice, in order that you may judge whether mine is a reasonable and sound advice, when I desire you to direct your studies to that part of it especially which is pathological.

Practical medical literature may be divided into that which is purely the result and product of observation, and into that which is the joint work of observation and of research into the nature of morbid processes.

I speak of that only as literature, whether ancient or modern, which is generally known and used and referred to, and has thus become classical by common consent. The part of medical literature bearing this character, which is purely the growth of observation, has many times struck me with wonder. For when I see that observation, exercised upon mere signs and external things, has so assorted and arranged them, so ascertained their import and described their succession, as if it possessed an insight into the inward processes out of which they arise, yet really possessing none; and when I see that, still guided by mere signs and external things, it has often given to powerful remedies the safest and the best direction; and that, concerning the event of diseases and the issues of life and death, it has been able to see clearly, and discriminate nicely, and prognosticate truly—I feel assured, that from the records of practical medicine may be adduced the highest instances of human sagacity and prudence. I have lately been turning over the Prænotions of Hippocrates, and the Epidemics of Sydenham, and this is the impression they have left upon my mind, concerning a class of writers of which they are pre-eminently the chief.

This part of medical literature, with which pure observation is conversant, receives few accessions from time to time; and this will hardly seem strange, when it is recollected that the same, or nearly the same, things which we now observe, have been observed by others, with the purpose of turning them to the same account, for more than two thousand years. The field of observation was well cultivated at an early period, and few names stand forth in any particular age, at subsequent periods, who have been really eminent in this department; and these have become fewer and fewer as the world has grown older.

Now, when I desire you to reserve the study and perusal of these writers for some future period, even until the time arrive when you have taken the treatment of diseases upon yourselves, do not conceive me to intimate that they are above the reach of your abilities. The truth is, that at present you have to learn their *language*. I do not mean the language of their words and phrases; these, indeed, are common words and phrases, but they smack of something beyond the common meaning.

This meaning you can only gradually pick up, by living in the same region where they lived—by seeing the same things, and conversing with the same objects, that they were conversant with. This region is the region of observation; and they who live in it, and they who live out of it, cannot understand each other. They can construe each other's phrases, but they have a very dark apprehension of each other's meaning.

Do not imagine that I am forming an exaggerated estimate of this class of writers, because you do not *now* hear of their being much read by medical men at any period of life. I know they are not much read, and I will tell you why: it is because the majority of medical men have no real love for the practical part of their profession. It is a labour to them to observe; therefore they are no observers. They cannot see clearly what they must strain their eyes to see at all; and I will tell you the reason of this also: it is because when they were students (pray take warning from what I say) medical practice was unpopular, and they never attended to

it; and they never were able in after-life to learn what they ought to have learnt in their youth. Their very faculty of observing was sound asleep when it should have been wide awake, and it could never afterwards be roused to discern more than the most obvious forms of things. No wonder then that the highest excellence in this same department of observation should have found few to appreciate it, and few to admire it.

But I hope better things from you. Only be diligent, and, at your time of life, and in so vast a field as this hospital, the very use and exercise of observation will naturally produce a taste and tact for observing; and then whatever you see in after-life you will see with profit, and draw sound experience from it; and not only so, but you will find yourselves of kindred minds with the great masters of our art, reading them, relishing them, and improving by them.

But there is another part of practical medical literature, viz. that which is the joint work of observation and of research into the nature of morbid processes—in a word, the pathological.

Observation, and mere observation, had been at work for ages, and the extent to which it had penetrated into the nature of diseases does, I confess, appear to me quite wonderful. But it could go no further alone; and it was obvious that, if diseases were ever to be better understood and better treated, observation must be aided by some new method of inquiry. That new method, in the course of time, was introduced, and is now popularly employed; it consists of research into morbid function and morbid structure, and is based upon the knowledge of healthy function and healthy structure. It is pathology founded upon physiology.

By the combination of these two methods, observation of symptoms, and a rigid research into the nature of morbid processes, the face of practical medicine has been completely changed, even in our day.

The advantage which the physician now has over the physician of old, is this: he has the same observation to guide him, and he has moreover a previous knowledge of the real condition of things, from which the immediate objects of observation derive themselves; and coming to his work of observation with that previous knowledge, he is able to make observation itself go as far again as it would go alone.

The fever, the cough, the sputa, the laborious breathing, the wasting of the flesh —these are the immediate objects of observation, and they at all times intimated fearful things to the physician of old, concerning diseases of the lungs. But effusions and congestions, and softening and hardening, and tubercles and vomicæ —these are the real things from which the fever, the cough, the sputa, the laborious breathing, and the wasting of the flesh, all derive themselves; and the physician now knows them all, and what they are in their origin, in their progress, in their termination, and which are capable of reparation and which are not; and knowing what they are, he has taxed his observation for the detection of them in the living man; and having detected them, he has further taxed his skill for a more exact application of remedies for their cure; and unquestionably he has often succeeded, both in detecting and curing, by the aids of pathology, what would have gone undetected and uncured if he had still worked by observation alone.

This pathology you must learn. Every day I go round the wards with you, I talk of things which must be quite unintelligible, if you are ignorant of morbid processes. There are forms of symptoms I am perpetually pointing out, which cannot be estimated except in their exact connexion with certain forms of disease previously understood. All the principal changes of structure which the lungs or the heart are capable of undergoing, must be well understood before you can appreciate any of the signs derived from auscultation or percussion. You may listen to the chest for ever and be no wiser, if you do not previously know what it is you are to hear. You may beat the chest for ever, and all in vain, unless you know what it is that is capable of rendering it now dull and now resonant.

In the diseases of various organs, the aid derived from pathology to practice is not always the same; but still there are few cases in which pathology does not contribute either to enlarge, or refine, or verify, our observation, and to direct our treatment with a surer aim.

This pathology, then, you must learn.

But pathology is not to be learnt only in the wards of an hospital, or in any one particular way. The sources of this knowledge are various, and so too are the methods of obtaining it. From lectures, from books, in museums, in dissecting-rooms, and by experiments upon the living or the dead body. It is conversant for the most part with demonstrable objects, which are capable of being measured, and weighed, and delineated. It is beginning to take the form of a science, and to be governed by certain rules.

In as many places, then, and in as many ways as it is capable of being learnt, you are at liberty to learn it.

And howsoever and wheresoever you learn it, you must bring it with you into the

wards of the hospital; and your observation will breathe a spirit into it and apply it to its proper use.

Thus patho'ogy will give greater effect and certainty to observation, and observation will test and confirm the truths of pathology; and both work together to the same end of improving the knowledge and treatment of diseases.

Such are the things which I have now called you together to communicate; and, simple as they really are, they have cost me some thought; and it is with some feeling of responsibility that I offer them, when I reflect that the advice which I am giving you now, at the entrance of your practical studies, according as it is good or bad, may lead or mislead you for life.

It is a matter of no trifling concern to the well-disposed student, that he should be put in the right way of using his own observation, and that he should be well aware of all the means which are calculated to aid or hinder him in his task.

With respect to the taking of cases, which is one chief mode in which the observation is exercised, I have advised that the student should not begin to take them too early, and before he has got a clear notion of the great cardinal symptoms which are the guides to diagnosis and treatment; yet that he should not begin to take them too late; that after he understands the import of symptoms, he should not allow his mind to rest too long in the abstract contemplation of them, but apply them at once to their use and exercise upon particular instances.

With respect to books, which are the chief aids or the chief hindrances to practical observation, I have told you what you must read with caution, and what you must not read at all—what you cannot read *now* without an injurious bias, but may read hereafter with profit; and what you may read *now* without harm, but hereafter with more certain advantage. But of all books and all studies, those, I have told you, are best calculated to promote the business of practical observation which are purely pathological and conversant with the nature of morbid processes.

Now pathology is a study for your whole life. But it must be begun here, and it is important that it should be begun in the right way; and I am interested in seeing that it is so, because every right notion of pathology will be a great assistance to you in the acquisition of that knowledge which is to be gained in the wards of the hospital, and every wrong notion a serious hindrance.

On some future day I will speak to you a little more at large upon this subject.

ON HYBERNATION.

By Marshall Hall, M.D.
F.R.S.E. M.R.I. &c. &c.

(Abridged from the Philosophical Transactions.)

That peculiar condition of certain mammalia during the winter season, which has been designated hybernation, has been aptly compared by various authors to ordinary sleep. In both, the respiration is diminished. This fact was first determined, in regard to sleep, by Messrs. Allen and Pepys. It obtains in a much higher degree in a state of hybernation. It is highly probable that in sleep, as in hybernation, the irritability of the muscular fibre becomes augmented. These two conditions of the animal system may therefore mutually illustrate each other.

Ordinary sleep is similar to the sleep of the hybernating animal; and the sleep of the hybernating animal is similar to that deeper sleep, or lethargy, which is designated hybernation. We are thus led to trace a connexion between the recurrent sleep of all animals, and the deep and protracted sleep of a few.

I. Of the Sleep of Hybernating Animals.

In the sleep of the hybernating animal, the respiration is more or less impaired: if the animal be placed in circumstances which best admit of observation, the acts of respiration will be found to have greatly diminished; if it be placed in the pneumatometer, little alteration is induced in the bulk of the air; if its temperature be taken by the thermometer, it will be found to be many degrees lower than that of the animal in its active state; if it be deprived of atmospheric air, it is not immediately incommoded or injured.

These facts I have observed in the hedge-hog, the dormouse, and the bat. If other authors have not made the same observations, it is because they have not been aware how easily this sleep is disturbed. To walk over the floor, to touch the table, is sufficient, in many instances, to rouse the animal, to re-produce respiration, and to frustrate the experiment.

The bat, which is a crepuscular or nocturnal feeder, regularly passes from its state of activity to one which may be

designated diurnation. The respiration and the temperature fail; the necessity for respiration is greatly lessened.

During the summer of 1831, I carefully observed a bat in this condition. If it were quite quiet, its respiration became very imperfect; its temperature was but a few degrees above that of the atmosphere; being placed under water, it remained during eleven minutes uninjured, and on being removed became lively and continued well.

I have more recently watched the habits of two hedgehogs, in a temperature varying from 45° to 50°. These animals alternately awake, take food, and fall asleep. One of them is frequently awake, whilst the other is dormant, and goes to sleep at a time that the other awakes, but without regularity. When awake the temperature of each, taken by pressing the bulb of a thermometer upon the stomach, is about 95°; when dormant, it is 45°; that of the atmosphere being 42° or 43°. The duration of this sleep is from two to three days, according to the temperature of the atmosphere. On the 4th of February, 1832, the temperature of the atmosphere being 50°, both the hedgehogs were dormant,—the temperature of one was 51°, and that of the other 52°; on the succeeding day the temperature of the atmosphere had fallen one degree, the temperature of one of the hedgehogs was 49°, whilst that of the other, which had become lively, had risen to 87°; on the succeeding day, the first had become somewhat lively, and its temperature had risen to 60°, that of the other being 85°, and that of the atmosphere 47°.

I have observed precisely the same alternations in the dormouse; except that this animal awakes daily in moderate temperatures, takes its food, and passes into a state of sleep, in which the respiration is greatly impeded, and the temperature little higher than that of the atmosphere.

On the day on which the observations were made on the hedgehogs, the atmosphere being 49°, that of two dormice was 52°; on the succeeding day, the external temperature being 47°, that is, lower by two degrees, the temperature of one of these dormice was 92°, and that of the other 94°; and only three hours afterwards, the temperatures were 60° and 70°, respectively, with a slight appearance of lethargy.

The hedgehog and the dormouse appear, in fact, to awake from the call of hunger, then to eat, and then again to become dormant, in temperatures which may be termed moderate. The bat, which could not find food if it did awake, does not undergo these periodical changes, except in the summer season. It appears to me, from the most careful observation, that there is every degree between the ordinary sleep of these animals and the most profound hybernation.

It is quite obvious, from these observations, that the ordinary sleep of hybernating animals differs from that of others, by inducing a more impaired state of the respiration and of the evolution of heat, with an augmented power of bearing the abstraction of the atmospheric air. This sleep probaby passes into true hybernation, as the blood which circulates through the brain becomes more and more venous, from the diminution of the respiration, and as the muscular fibre of the heart acquires increased irritability.

It is absolutely necessary, in comparing the powers of hybernating and other animals, of evolving heat, accurately to observe whether there be any degree of sleep. Mr. Hunter's and M. Edwards's experiments are extremely deficient, for want of this attention. Mr. Hunter, comparing the common mouse and the dormouse exposed to a very low temperature, observes, that the heat of the former "was diminished 16° at the diaphragm, and 18° in the pelvis, while in the dormouse it gained five degrees, but lost upon a repetition." The explanation of these facts is afforded by noticing that when the dormouse increased in temperature, it was "very lively," but on the "repetition" it had become "less lively." M. Edwards omits to mention whether the hybernating animals in his experiments were disposed to be lively or dormant, or whether they had recently recovered from a dormant state. Without a peculiar attention to this point, no correct result can be obtained. The hybernating animal in a state of vigour and activity, is a totally different being from the same animal disposed to become dormant.

II. Of true Hybernation.

I now proceed to the detail of my observations upon actual hybernation, and especially upon the state of the respiration and the irritability, of the sensibility, the circulation, and the digestion, in this singular condition of the animal economy.

1. *Of the Respiration.*

The respiration is very nearly suspended in hybernation. That this function almost ceases, is proved, 1st, by the absence of all detectable respiratory acts; 2ndly, by the almost entire absence of any change in the air of the pneumatometer; 3rdly, by the subsidence of the temperature to that of the atmosphere; and 4thly, by the capability of supporting, for a great length of time, the entire privation of air.

1. I have adopted various methods to ascertain the entire absence of the acts of respiration. I placed bats in small boxes, divided by a partition of silk ribbon, the cover of which consisted of glass, and in the side of which a small hole was made, to admit of placing a long light rod or feather under the animal's stomach. The least respiratory movement caused the extremity of this rod to pass through a considerable space, so that it became perfectly apparent.

Over the hybernating hedgehog I placed a similar rod, fixing one extremity near the animal, and leaving the other to move freely over an index. During hybernation not the slightest movements of these rods could be observed, although they were diligently watched. But the least touch, the slightest shake, immediately caused the bat to commence the alternate acts of respiration, whilst it invariably produced the singular effect of a deep and sonorous inspiration in the hedgehog. It is only necessary to touch the latter animal to ascertain whether it be in a state of hybernation or not: in the former case there is this deep sonorous inspiration; in the latter, the animal merely moves and coils itself up a little more closely than before. After the deep inspiration, there are a few feeble respirations, and then total quiescence. The bat makes similar respirations without the deep inspiration, and then relapses into suspended respiration.

2. As the acts of respiration are nearly suspended during hybernation, so are the changes induced in the atmospheric air.

On January the 28th, the temperature of the atmosphere being 42°, I placed a bat in the most perfect state of hybernation and undisturbed quiet, in the pneumatometer, during the whole night, a space of ten hours, from 1h. 30m. to 11h. 30m. There was no perceptible absorption of gas.

Having roused the animal a little, I replaced it in the pneumatometer, and continued to disturb it from time to time, by moving the apparatus. It continued inactive, and between the hours of 1h. 20m. and 4h., there was the absorption of one cubic inch only of gas.

Being much roused at four o'clock, and replaced in the pneumatometer, the bat now continued moving about incessantly; in one hour, five cubic inches of gas had disappeared. It was then removed. A further absorption took place of ·8 of a cubic inch of gas.

Thus the same little animal, which, in a state of hybernation, passed ten hours without respiration, absorbed or converted 5·8 cubic inches of oxygen gas into carbonic acid, in one hour, when in a state of activity. In an intermediate condition, it removed one cubic inch of oxygen in two hours and forty minutes.

[Various other experiments gave analogous results.]

It is important to remark, that the registration of the quantity of absorption in these experiments was not begun until several hours after the animal had been enclosed within the jar of the pneumatometer, so that the absorption of the carbonic acid, always present in atmospheric air, was excluded from the result.

It may be a question whether the slight quantity of respiration I have mentioned be cutaneous. The absence of the acts of respiration would lead us to this opinion. But it may be observed, that these acts have not been watched, and can scarcely be watched continuously enough, to determine the question of their entire absence. Some contrivance to ascertain whether the rod has moved along the index during the absence of the observer, would resolve every doubt upon this interesting point. And I think it right to remark, that after the apparent total cessation of respiration, as observed by the means which have just been described, there is probably still a slight diaphragmatic breathing. I am led to this conclusion, by having observed a slight movement of the flank in a favourable light, unattended by any motion of the thorax or epigastrium.

3. Much precaution is required in ascertaining the comparative temperature of the animal with that of the atmosphere. The slightest excitement induces a degree of respiration, with the consequent evolution of heat.

The plan which is best adapted to determine this question in regard to the bat, and which I have adopted, together with every attention to preserve the animal quiet and undisturbed, is the following:—A box was made of mahogany, with a glass lid, divided horizontally at its middle part, by a fold of strong ribbon, and of such dimensions as just to contain the animal. The bat was placed upon the ribbon, and inclosed by fixing the lid in its place. Being lethargic, it remained in undisturbed quiet. A thermometer, with a cylindrical bulb, was now passed through an orifice made in the box on a level with the ribbon, under the epigastrium of the animal, and left in this situation.

It was only now necessary to make daily observations and comparisons between this thermometer and another placed in the adjacent atmospheric air. The layer of silk, and the portion of air underneath, protected the animal from the immediate influence of the temperature of the table, on which the box was placed.

[Thirty-two observations are next detailed. In twenty-nine, the temperature of the animal and of the atmosphere were identically the same; in three, the animal heat was half a degree higher.]

From this it is obvious that the temperature of the hybernating animal accurately follows that of the atmosphere. When the changes of temperature in the latter are slight, the two thermometers denote the same temperature. If these changes are greater and more rapid, the temperature of the animal is a little lower or higher, according as the external temperature rises or falls; a little time being obviously required for the animal to attain that temperature.

Similar observations were made during the first three days of February. On the 4th, however, the temperature of the atmosphere rose to 50½°; that of the animal was now 82°, and there was considerable restlessness. On the 6th, the temperature of the atmosphere had fallen to 47½°, and that of the animal to 48°, whilst there was a return of the lethargy.

After this period there were the same equal alterations of temperature in the animal and in the atmosphere, observed in the month of January.

It is only necessary to add to these observations, that the internal temperature is about three degrees higher than that of the epigastrium. In two bats, the external temperature of each of which was 36°, a fine thermometer, with an extremely minute cylindrical bulb, passed gently into the stomach, rose to 39°.

The following experiments, made by the celebrated Jenner, illustrate this point:—

"In the winter, the atmosphere at 44°, the heat of a torpid hedgehog at the pelvis was 45°, and at the diaphragm 48½°.

"The atmosphere 26°, the heat of a torpid hedgehog, in the cavity of the abdomen, was reduced so low as 30°.

"The same hedgehog was exposed to the cold atmosphere of 26° for two days, and the heat of the rectum was found to be 93°; the wound in the abdomen being so small that it would not admit the thermometer.

"A comparative experiment was made with a puppy, the atmosphere at 50°; the heat in the pelvis, as also at the diaphragm, was 102°.

"In summer, the atmosphere at 78°, the heat of the hedgehog, in an active state in the cavity of the abdomen, towards the pelvis, was 95°; at the diaphragm, 97°.

There is an error in the admirable work of M. Edwards, in relation to the present subject, which it is important to point out. M. Edwards first ascertained the interesting fact, that the very young of those species of animals which are born blind, lose their temperature if removed from the contact of their parent; and justly concludes that they have not sufficient power of evolving heat, to maintain their natural temperature when so exposed. M. Edwards then subjected hybernating animals to the action of cold, and observing that their temperature also fell, he concludes that they, like the very young animal, have not the faculty of maintaining their temperature under ordinary circumstances.

It is remarkable that this acute physiologist did not perceive the error in this reasoning. In no instance does the young animal maintain its warmth, when exposed alone to the influence of an atmosphere of moderate temperature. Can this be said of the hybernating animal? certainly not. In ordinary temperatures, the hybernating animal maintains its activity, and with its activity, its temperature. The loss of

temperature in this kind of animal is an induced condition, occasioned by sleep.

4. It is in strict accordance with these facts, that the lethargic animal is enabled to bear the total abstraction of atmospheric air or oxygen gas, for a considerable period of time.

Spallanzani placed a marmot in carbonic acid gas, and makes the following report of the experiment in a letter to Senebier: "Vous vous ressouviendrez de ma marmotte qui fut si fortement léthargique dans l'hiver sévère de 1795; je la tins alors pendant quatre heures dans le gaz acide carbonique, le thermometre marquant—12°, elle continua de vivre dans ce gaz qui est le plus mortel de tous, comme je vous le disais: au moins un rat et un oiseau que j'y plaçai avec elle y périrent à l'instant même. Il parait donc que sa respiration fut suspendue pendant tout ce tems-là. Je soumis à la même expérience des chauve-souris semblablement léthargiques, et le résultat fut le même."

A bat which was lethargic in an atmosphere of 36 deg. was immersed in water of 41 deg. It moved about a little, and expelled bubbles of air from its lungs. It was kept in the water during sixteen minutes, and then removed. It appeared to be uninjured by the experiment.

A hedgehog which had been so lethargic in an atmosphere of 40 deg. as not to awake for food for several days, was immersed in water of 42 deg. It moved about and expelled air from its lungs. It was retained under the water during 22½ minutes. It was then removed. It appeared uninjured.

It seems probable that the motions observed in these animals were excited through the medium of the cutaneous nerves.

The power of supporting the abstraction of oxygen gas, or atmospheric air, belongs solely to the hybernating state, and is no property of the hybernating animal in its state of activity. After having found that the dormant bat, in summer, supported immersion in water, during eleven minutes, uninjured, I was anxious to know whether the active hedgehog possessed the same power. I immersed one of these animals in water. It expired in three minutes, the period in which immersion proves fatal to the other mammalia. Sir Anthony Carlisle has, therefore, committed an error, somewhat similar to that of M. Edwards, when he asserts that "animals of the class Mammalia, which hybernate and become torpid in winter, have at all times a power of subsisting under a confined respiration, which would destroy other animals not having this peculiar habit." The power of bearing a suspended respiration is an induced state. It depends upon sleep or lethargy themselves, and their effect in impairing or suspending respiration; and upon the peculiar power of the left side of the heart, of becoming veno-contractile under these circumstances.

[To be continued.]

GREEN PERSPIRATION.

Case *in which* Copper *was detected in the* Perspiration.

[Communicated by Sir Henry Halford.]

Sir,

I have great pleasure in laying before you the particulars and result of a case of green perspiration, in which, when I had last the honour of an interview with you, you were pleased to express much interest.

Miss ——, æt. 14, had for some months evinced much general debility, when, in September last, she was seized with an attack of rheumatic fever, which yielded to remedies slowly and unsatisfactorily. After some days, during which the perspiration was considerable, my attention was called to a collection of light green perspiration between the toes, and underneath the nails of the young lady's feet, whilst the same appearance was observable in a fainter degree on the upper, but more especially the under surface of the foot. Having collected a sufficient quantity of this matter, I submitted it to the examination of a scientific and practical chemist. His first experiments disproved my suspicion of its containing iron, and after fusion in a platina crucible, the mass, on being broken and separated with a drop of water, was found to consist chiefly of siliceous matter, intermixed with which (to my great satisfaction) small glittering spangles of copper were sufficiently evident. The experiment was repeated with a smaller quantity of the secretion, and with the same result, leaving me in possession of some minute spangles of the metal.

It was thus clear that the green co-

lour was attributable to an acetate of copper, and it only remained to investigate the source of this remarkable fact. An examination of the culinary vessels in common use (and in which the young lady's breakfast of milk was regularly prepared) solved the mystery to my satisfaction, inasmuch as the lining of tin had disappeared upon half the extent of their surfaces,—leaving the copper exposed. It is somewhat singular, that a day or two previous to this discovery, the mother of the patient had shewed to me her tongue, which was swollen and pale in such a degree that I at once said, "You must have been partaking of mushrooms, or some poisonous food:" yet it is fair to state that the other members of the family, although they had been ailing in one or two instances, betrayed no symptoms corroborative of the cause of the young lady's peculiar state. It appears to me, sir, that from the above case some questions of interest arise; namely,

It being presumed that the copper was so gradually introduced into the system as to prevent the necessary and immediate consequences of so virulent a poison under other circumstances, was it thus introduced in the form of an acetate? or was the acetate or lactate produced subsequently by the action of the lactic acid of the perspiration?

I would also ask, if it were possible that the action of sudorific medicines could have elicited that in this young lady, which, under similar circumstances, may have been in a like manner produced in others (at least those who partook of milk, &c. thus cooked) of the family?

I have searched in vain among the older writers for detailed cases of this nature. Sauvages gives them a place in his Nosology, but does not speak of them at large, referring to Borelli for examples of the "sudor colore viridi."

I am, sir, with feelings of much
respect and obligation,
Your obedient and humble servant,
JOHN PRICHARD.

CHOLERA IN PARIS AND BERLIN—CHARCOAL AS A REMEDY.

Extract of a Letter from M. MOREAU DE JONNES, *dated Paris, Nov.* 10, 1832.

"THE cholera is reduced here to a few isolated cases. The mortality during the month of October, caused by that disease, has been as follows:—

In their own houses	33
In the civil hospitals.....	33
In the military hospitals	0
Total deaths	66

"The Journal of Commerce of *Anvers*, (Antwerp) has inserted a letter from Berlin, dated 31st October, announcing that the cholera had just broken out in that capital with greater violence than ever, and that seven hospitals were already filled with sick.

"Dr. Garrandan, of Arras, writes to me, that having seen in my report to the Supreme Council of Health that powdered charcoal had been successfully used on board some American ships, whose crews were attacked with cholera, he employed that remedy in the department of the *Pas de Calais*. He administered the fourth part of an opiated enema, containing a tablespoonful of wood charcoal in powder.

"In twelve cases, of which he gives the details, the cure was complete and immediate. In several cases he omitted the opium, with the same success.

"Should you have occasion to make use of the remedy, be kind enough to let me know the result."

ANALYSES & NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

Practical Observations in Midwifery, with a selection of Cases. Part the Second. By JOHN RAMSBOTHAM, M.D. &c. &c.

IT is now some years since the appearance of the first part of the work before us, and which was very favourably received by the profession both at home and abroad, having, indeed, constituted a valuable addition to obstetrical medicine. It is refreshing to turn from the pompous puerilities, with which the press has recently teemed in the shape of "Outlines" and "Manuals" of midwifery, to the observations of Dr. Ramsbotham. We have here some of the most important subjects connected with parturition fully discussed by one,

who speaks not merely of what he has read, but of what he himself has seen and done, and the result is correspondingly satisfactory, in that the observations are really "practical." The different forms of preternatural labour are fully discussed; and under the head of "shoulder presentation" are some very useful directions for the process of turning; we have also some important instances of those distressing cases wherein, from the attempt having been unskilfully made, the child becomes so impacted as to require to be removed piecemeal. Uterine hæmorrhage is likewise discussed; and among other circumstances, the unusual one of the placenta passing down before the head of the child, is described. Puerperal convulsions, with the appropriate remedies, are spoken of according as they occur before labour, during the process, or after it is over. Abortion and extra-uterine pregnancy, also come under notice, and are fully considered. Retroversion — polypus — rupture of the uterus — are severally described, and we have three cases of the latter detailed in which recovery took place.

The work ought to be on the shelf of every man in the kingdom practising as an accoucheur.

Leçons sur le Cholera Morbus faites du College de France. Par M. T. Majendie. Paris, Mai 1832.

It is not our intention to enter into any lengthened analysis of these Lectures; but as they have been put forth with very considerable pretensions, we shall give one or two short extracts, by which the reader will be enabled to judge of the consistency of the statements, and actual claims of the author to superiority in his plan of treatment.

"Of six hundred cholera patients admitted into the ward of St. Monica, at the Hôtel Dieu, under my care," says the Professor, "with the exception of thirty-eight, who died on their litters, *all* became warm, and *in all* the circulation appeared after the employment of the means already mentioned." These means were *Magendie's Punch*, composed thus:—

Infusion of Camomile .	1 pint.
Alcohol	2 ounces.
Sugar	1 do.
Lemon Juice	q. s.

Frictions, with camphorated spirit, ammonia, and turpentine. Warm bed. Bags of hot sand.

At page 235, the Professor writes thus:—"In my private practice, in which I treated many patients at the commencement of the epidemic, I have been fortunate enough *not to lose one*, even of those who had reached the very advanced periods of the disease."

But with regard to his public practice, checked as the returns necessarily are by the officers of the Hospital, we find the following, at page 233:—"Five hundred and ninety-four cholera patients were admitted into my wards, and underwent my mode of treatment: three hundred and sixty-four were cured; two hundred and eight died"! These discrepancies are sufficient to prevent us attaching much importance to the views of the writer.

MEDICAL GAZETTE.

Saturday, November 17, 1832.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

Cicero.

THE MEDICAL SCHOOLS AND DR. ELLIOTSON.

Our readers must have perceived from the advertisement on the wrapper of our journal last week, and from our notice referring to it, that we have the misfortune to be at issue with Dr. Elliotson. The immediate subject of the difference is connected with the observations on his Introductory "Address," contained in our leading article of the 3d instant; and as it is a very important step towards the decision of any question, to know exactly what the contested points are, we take leave to state them distinctly at the outset.

The learned Professor of Medicine in the London University, in the course of his Introductory Lecture, and which he has since published, (Longman & Co.) made use of these words:—

"In the medical department, the superiority of the plan of our University

over that, not only of Oxford and Cambridge, but of every other school in England, is very conspicuous. * * * The superiority of the plan of our University over that of all other English medical schools consists in the copiousness and extent of the information afforded. A course of lectures of six months' duration, and of almost every day in the week, upon the practice of medicine, the practice of surgery, anatomy and physiology, chemistry, materia medica and pharmacy, and all remedial means, is absolutely necessary to afford any thing like due information to the pupil on these respective subjects. Courses of only three or four months' duration, and consisting only of three lectures a week, must be very superficial, and leave the hearer but a smatterer, so that to become well informed, he must have industry enough to read extensively, and draw from other sources of information."

From this quotation it will be perceived that Dr. Elliotson was not contented with speaking of his own institution in such terms of commendation, as might without any violation of propriety or good taste have been bestowed upon it, but he insists upon the existence of great and "very conspicuous" superiority, and, consequently, charges the other schools with being inferior; for the expression "superiority" implies, not only comparison, but comparison to the disadvantage of others. But, further, he illustrates the alledged superiority by contrasting a course "of six months' duration, and of almost every day in the week," with courses "of three or four months' duration, and only three times a week." Now either Dr. Elliotson thereby meant to imply, that the courses he had enumerated were all at the London University of the duration he described as "absolutely necessary," and that elsewhere they were not so; or else what he did mean is not intelligible from his words. Then we are farther told that courses of a certain shorter duration must be "very superficial," and leave the hearer but a "smatterer;" so that to acquire the requisite degree of knowledge, he must "draw from other sources of information." This, to our simple apprehension, is a sweeping sentence of condemnation passed on all the medical schools in England, and means, as distinctly as it can with any show of modesty be expressed — the pupil who goes any where except to the London University will be taught according to an inferior plan, and which will leave him "but a smatterer."

In the article which has given so much offence to the learned Professor, we answered this attack upon the other schools; and the inferences we drew were as follow:—

"It is impossible for us to read these statements without perceiving that the learned author is not fully aware of the state of the other medical schools, else would he not have passed upon them this general charge of inferiority, without one qualifying expression, or one redeeming exception. There are, however, two objections which may be made to the Doctor's positions; namely, first, that the "plan" is really by no means so different in the other principal schools as his exclusive language would lead the public to suppose; and secondly, where any difference exists, it is far from being so "very conspicuous" on which side the superiority lies."

Here, then, are the points at issue,— *and be it remembered that Dr. Elliotson is the aggressor: — he* charged all the medical schools in England, without exception, with inferiority; founding the alledged superiority of his own on the existence of a "plan," which he describes: — *we* again assert, that the plan is not so different from that pursued at certain other schools as his language would lead the public to suppose; and that where there is a difference, it is matter of reasonable doubt on which side the superiority lies.

In proceeding to discuss these questions, we shall, first, in courtesy, give

to Dr. Elliotson the full benefit of his reply to our former article, requesting only that our readers will fix their minds upon the real subject of discussion as above stated, and discard, at least for the present, the irrelevant matter with which the Doctor, in his warmth, has encumbered the statement of his case:—

To the Editor of the Medical Gazette.

Sir,

Nothing would distress me more than to have made a misrepresentation, especially if to the disadvantage of others.

(1.) In your last number [Nov. 3d] you evidently accuse me of misrepresentation, in saying that the difference between the mode of instruction in the University of London and in other London medical schools, is, that our courses last six months, and are delivered almost every day in the week, while in the others two courses are given in the same period, and are delivered but three times a week. If I was in error, the account of the prospectuses printed in the *Lancet* is incorrect, and all to whom I have spoken on the subject are misinformed.

(2.) I request you to acquaint me whether at St. Thomas's, St. Bartholomew's, the London, Guy's, St. George's, King's College, &c. the lectures on the practice of medicine, on chemistry, on materia medica, &c. are given more frequently than three times a week; and whether each course lasts six or seven months. I request you to specify the London schools in which the courses on these subjects consist of as many lectures as at the London University, and in which the total number of lectures (not repetitions of lectures) on medical subjects, approaches to the number delivered in the University; and to specify, also, the nearness of the approach.

(3.) You accuse me of error in regard to the surgical course. Now I did not allude especially to the length of any single course, but to the general plan of our school; and allow me to inform you, that Mr. Professor Cooper frequently lectured four and five times a week, and that his course consisted of above a hundred lectures.

(4.) You accuse me of error in stating that another superiority of our plan consists in occasional examinations. I beg to inform you, that our examinations are not occasional, but systematic and frequent—upon the subject of every lecture, and conducted with the same care and regularity as the lectures themselves. I request you to mention the other London school in which there is the same number and systematic regularity of examinations of the students attending *every* class, and where the inducement to submit to these examinations is made so powerful.

(5.) You misrepresent me when you tell your readers, that I state it as a superiority of our school that we illustrate by specimens, &c. My argument was, that, as every lecture is illustrated, there must be more illustration in our extended course than there can be in short courses.

(6.) If you found the Edinburgh lectures on materia medica an infliction, I pity from my heart the sufferings you must have endured for six long dreary months. To me the course of Dr. Home was a daily delight. From no lectures did I derive more solid information and pleasure; from few, so much: and I must say that, were I to deliver lectures on materia medica, I should find six months not a day too much for giving my pupils all the information they ought to possess, not merely on the poor list of drugs in the London Pharmacopœia, within which your ideas of a course on materia medica must be limited, but upon all other excellent medicines—upon all that relates to the operation of many, as poisons—upon diet—upon exercise—upon mineral waters—upon baths—upon climates—and whatever else is employed remedially,—or, in the words of my Address, "upon materia medica and pharmacy, and all remedial means."

(7.) If students have ever requested a short course on anatomy and physiology, instead of an extended one, I lament it. The coarse anatomy and physiology that are sufficient for operative surgery, may be taught in three or four months. But I defy any one to teach minute and philosophical anatomy and physiology, such as a man of education and science would desire, in less than almost daily lectures for six months. How you must lament such a request from students is proved by what you said on October the 20th, at page 92:—"There is one step that ought to be taken in time—and the sooner the better, for the sake of our anatomical character: the measure we allude to is the necessary one of establishing courses of a fitting length. Nobody will misunderstand us on this

head: our protest is directed against the inconceivably absurd regulation of countenancing *three months'* courses. Who that has ever handled a scalpel and forceps has not been at once convinced of its absurdity?"

(8.) I am anxious that you should remember, that I contended for no superiority on the part of our teachers; but merely for the superiority of the *Edinburgh plan* which had been adopted at the University. That this plan is superior, appears proved by the unexampled success of the school,—by the number of new students this year being actually above double the number of new students last year. We, the professors, are conscious of being not a whit superior to other teachers. Our success, therefore, must be ascribed to our plan.

(9.) In concluding, I trust you will perceive that any one whose intellect could draw inferences so erroneous, and whose moral feelings could allow him to make assumptions so unjust, cannot be depended upon for the statements and reasonings of his lectures, and that therefore it cannot conduce to the character of your Gazette to continue them,—though they have doubled your sale. Neither will it be any thing more than you will approve, if one, "to whom the diffidence which ever attaches to true merit" (you say) "must be familiar, and who no doubt can appreciate the reluctance with which those who are devoted to the pursuits of science obtrude themselves and their pretensions on the notice of the public," and who, you well know, repeatedly entreated you not to publish his lectures, declines, with becoming modesty, to assist in giving himself farther publicity by continuing to correct the copy of his lectures taken by your short-hand writer.

I remain, &c.

JOHN ELLIOTSON.

37, Conduit-Street,
Nov. 6, 1832.

[The following addition to the above has been forwarded to us by one of our publishers: it is cut out of a note,—not addressed to the Editor.]

(4. *bis.*) I never asserted that examinations are instituted solely at the University, but argued, that where they are instituted, they will be more numerous if the courses are long. My words were:—"The utility of frequent examinations is doubled by a full course of lectures. There must necessarily be double the number of examinations on the subjects of the course, so that the student is examined on a far larger number of topics, and far more deeply and minutely in each, because the examinations will be commensurate with the lectures."

Thursday morning.

We shall answer the paragraphs of the above letter *seriatim.*

1. We did not accuse Dr. Elliotson of misrepresentation, or any where make use of that expression: we did but state our conviction, "that the learned author was not fully aware of the state of the other medical schools:" and we may now add, that the source from whence he tells us his information was derived fully accounts for this ignorance. It is quite notorious that the *Lancet* has long been engaged in endeavouring to write the other schools *down*, and the University *up;* and we cannot but express our astonishment that Dr. Elliotson should for one moment have thought of trusting to such authority.

2. The whole gist of the letter lies in the second paragraph; in which Dr. Elliotson demands a categorical answer as to whether the number of lectures constituting a course at other schools, equals, or even approaches, to that in the London University? We answer thus:—Anatomy is given in an extended course, which is continued during the whole season—above seven months—at the schools of St. Thomas's and Aldersgate-Street, and was given last year in the same manner at Guy's; the plan having there been changed this season at the request of the pupils,—a fact we added in a postscript, not, as Dr. Elliotson would erroneously imply, for the purpose of expressing an opinion, but merely to record the fact, and to avoid the slightest appearance of over statement. At St. Thomas's—Dr. Elliotson's own hospital—the anatomy is given on what ap-

pears to us an excellent plan—namely, in one extended course of eight months' duration; six months being devoted to lectures without repetition, and two months to going over all the most important parts a second time. Surgery is given in extended courses at St. Bartholomew's, Guy's, St. George's, and King's College. The practice of physic is given in one extended course at King's College, at St. George's, and at the London Hospital. Chemistry also is given in one extended course at King's College and the London Hospital. The relative proportion of lectures at the above places, as compared to those at the London University, on the corresponding subject, varies, but the average is as a course delivered three times a week for seven months and a half, to a course delivered four times a week for six months. On anatomy, the number of lectures at Aldersgate-Street and at St. Thomas's greatly exceeds that at the London University, being in the one as five in the week to four, in the other as six in the week to four, and in both those schools the courses are continued for a longer period.

We must here remark in addition, that the questions which we have answered above are disingenuously put in Dr. Elliotson's letter; first, because they do not tally with the corresponding part of his "Address," which, as will be seen from the extract above quoted, included *anatomy* and *surgery;* and secondly, because he inserts chemistry, of which we said nothing (although we have here answered on that point also), and materia medica, concerning which we not only admitted that it was not spun out to six months any where in England, except at the London University, but argued that it was not judicious that it should be so: thus he blinks an important part of the question in the first instance, and then calls upon us to say where that exists which we stated neither was nor ought to be.

3. The third paragraph is very remarkable. Dr. Elliotson says, that he "did not allude especially to the length of any single course," and that we therefore accuse him wrongfully of being in error with regard to the surgery. Now, Dr. Elliotson's words are, "a course of lectures of six months' duration, *and of almost every day in the week*, upon the practice of medicine, *the practice of surgery*," &c.: and we ask any candid man to say whether the impression necessarily conveyed by this language was not, that the course of lectures on surgery was delivered at the London University *almost every day in the week*. But it is added, in explanation, that Mr. Cooper frequently lectured four and five times a week. Dr. Elliotson may rest assured, that if this had occurred *frequently*, the Council, with all their "Faculties" about them, would not have stated in their prospectus that the lectures were only delivered on "Monday, Wednesday, and Thursday." We have no doubt that the simple fact amounts to this—that when he is going over the operations, and perhaps also towards the end of the season, Mr. Cooper finds it necessary to give additional lectures, to get his course completed within the specified time,—just as almost invariably occurs at other schools. But it is not with regard to the surgical course alone that Dr. Elliotson's language is so loose as to mislead: the fact is, that none of the lectures are delivered so frequently as his expressions would warrant us in inferring. Who, for example, on reading that "a course of lectures of six months' duration, *and of almost every day in the week*," was absolutely necessary, would be prepared to find not only that one of the principal courses (surgery) is delivered only three times a week, but that, systematically,

none of the medical professors lecture more than four times in the week! Yet such is the matter of fact; for no business is done on Saturday, and the examinations are substituted once a week *for* lectures, not given in addition to them, as elsewhere, thus leaving for the lectures almost three days a week less than is declared to be "absolutely necessary."

4. In the next place, the learned lecturer takes umbrage at our calling the examinations "occasional," which he states are "frequent and systematic." Be it so hereafter; but in the Address he himself says they take place "every week or ten days," which we submit was not improperly designated by being called "occasional." We believe that there is no school in London in which examinations are not now given in connexion with most of the courses; but we are not able to speak so precisely on this point as the others, because the examinations are not always set forth in the prospectuses, even of those schools where we have ascertained that they are systematically given. It will be seen, however, that the Doctor makes the word *every* emphatic; and he will be gratified to learn that, at the great rival school, King's College, examinations are regularly and "systematically" given in *every* course! The last question in the paragraph—namely, where is the inducement to submit to these examinations made so powerful?—is triumphantly put; and the Doctor justly regards it as unanswerable, for they are made preliminary to a diploma, with a degree in the reversion. Well then may the Doctor ask, where else this is done? Where else indeed is there to be found an instance of a joint-stock company having the presumption to assume the name, and pretend to be able to exercise the privileges, of a University? This may do as a bait for pupils, but as for us—"old birds are not easily caught with chaff."

5. With regard to the illustration of lectures by specimens, Dr. Elliotson's original words are—"and when it is considered that these lectures are abundantly illustrated with specimens, drawings, engravings, models, preparations, experiments, and operations, the superior advantage of an ample course of lectures over one so short that no subject can be fully treated, and some must be almost or entirely passed over—so short as rather to indicate to the student what he has to learn, than teach it him—must be evident." Now we certainly thought that Dr. Elliotson, by informing us that "*these* lectures" were abundantly illustrated, while others were so short that no subject could be fully treated, meant to claim a superiority for the plan of illustration; but he says not; and the sentence is so confusedly expressed, that it may possibly admit of his interpretation as readily as our's; and the question is so unimportant that we care not a jot which is given to it.

6. As to what follows, about the value of Dr. Home's lectures, and the length to which a course on materia medica ought to extend, they are matters of opinion merely: we spoke from experience of what takes place in Edinburgh, (and we might have added Dublin,) when we said that to spin out the course for six months requires the introduction of subjects foreign to its proper business; and Dr. Elliotson, in his enumeration, is fain to include what belongs to two other courses—namely, poisons, which are in the province of the teacher of forensic medicine, and pharmacy, which belongs to the chemist.

7. We perfectly agree with what follows about anatomy. The quotation from a former leader of our's on the subject, however, might indeed have been to the point, if we had argued first in favour of long courses, and then in favour of short ones; but we had previously and very distinctly given our

opinion in favour of the former; and, in the article which Dr. Elliotson answers, we merely shewed that a difference of opinion existed among the lecturers with regard to this point. But the extract is wholly irrelevant to the present argument — the question not being what Dr. Elliotson or we approve, but whether there be, or be not, any other school in England, besides the London University, where an extended course is given.

8. The Edinburgh plan, which is here spoken of as if it were identical with that of the London University, is by no means the same, inasmuch as the courses there consist of many more lectures—to the exclusion of examinations, which constitute an important part of the London system; so that the difference between it and the system adopted at the London University, is actually greater than between that of the latter and the other metropolitan schools.

9. The last paragraph can only be looked upon as an ebullition of temper. We no where made any, the slightest, insinuation against Dr. Elliotson's honour or morality; nor is there a single passage in our leader, except the concluding one, at which any reasonable man, however sensitive, could possibly take umbrage: it is that in which we alluded to the diffidence of men of science, and the reluctance with which they usually obtrude themselves upon the public; an allusion which, considering that circumstances rendered it open to be interpreted ironically, was perhaps rather too provoking. By the by, even here the Doctor affords a little specimen of that sort of inaccuracy which has led to the present discussion: he represents us as saying that he must be familiar with the diffidence which ever attaches to *true* merit. The "*true*" is not our's: and his *interpolation* gives the sentence a degree of acrimony which it had not in the original, and which we therefore disclaim.

Dr. Elliotson would imply that we have dealt unhandsomely by him in publishing his lectures: how far he is warranted in that imputation the subjoined documents will shew. The learned Professor also informs us that they have doubled our sale. That our publishing his clinical lectures doubled his practice, we have his own authority for affirming*; but the counterpart of the story is not correct. Our circulation has progressively reached its present high standard under the combined effect of the contributions of many of the most eminent professional men in the kingdom;—nor do we hesitate to add Dr. Elliotson to the list of our valuable contributors: had we not thought well of his lectures, we should not have inserted them, but that they doubled the effect of what had been done by all those distinguished men who have enrolled themselves among our correspondents, or made such a change as in any degree to warrant his assumption, is wholly unfounded; and we can only say that whoever so imposed upon the learned professor must have been practising upon what he knew to be his weak side†.

Such, then, is our answer to Dr. Elliotson: how far he was justifiable in his sweeping denunciation of all the schools, provincial and metropolitan, except his own—and how far we were warranted in venturing to assert that the learned Professor was not fully aware of the actual state of those institutions (for

* In his introductory lecture last year, Dr. Elliotson having stated that his practice had been improved by the publication of his clinical lectures, used these words:—"Last year the Lancet published them all: the MEDICAL GAZETTE followed its example, and my practice has now doubled a third time."

† We perceive that the Doctor states his authority to have been the "Gazette printer." We repeat our explanation, *whoever* his informant may have been, and refer him to the publishers as alone capable of judging on such a point.

so far only did our imputation extend)—we leave it for others to decide. As the matter now stands, he has made his attack, and we have answered—he has had his reply, and we our rejoinder. To carry on the discussion in the tone which it has assumed, would neither be very edifying nor instructive to our readers; but were it otherwise, as Dr. Elliotson has adopted a step so unusual on such occasions, as that of answering in one periodical an article which had appeared exclusively in another—a periodical, too, in which he well knew that his side of the question alone would ever be set forth; as he has addressed our readers against ourselves on the wrapper of the Gazette; as he has even thought fit to carry this discussion into the lecture-room, and submit his grievances to the arbitration of his pupils in an ex-parte statement, where argument was abandoned to attribute motives to his opponents—we say, that under such circumstances it is in vain to look for any thing like a cool and dispassionate investigation of the points at issue: the learned Professor will therefore excuse us for requesting, that, if he has aught farther to adduce, he may confine himself to the new channels he has opened for communicating with the public; for here, as regards the pages of this journal, the controversy must close.

Before we conclude, there is one point more to which we must advert—a point which we understand was referred to by Dr. Elliotson, in his appeal to his class. It would appear that he regarded the sketch in the "Chapter on Introductories," with which we commenced the present volume, as a caricature of himself and his address. If so, he is mistaken; it was planned before the opening of the session, and was intended only as a general satire on the system of egotism and puffing too frequently adopted on such occasions. The allusion to degrees was intended for the University indeed, but not for the Professor, and was borrowed from a former article of our own, published long ago (vol. vi. p. 379.) If the tenor of his address brought it more close than that of most other lecturers to our imaginary "Introductory," it is to be attributed to his having, more than others, fallen into the errors which we wished to expose. Thus much we say in justice to ourselves, because, as a matter of taste, we would not have it supposed that we purposed either to caricature any individual or to parody any particular lecture: indeed it bears internal evidence of being intended as of general application.

We take leave of Dr. Elliotson, then: not without some regret, because our journal has been, and will continue for some time to be, indebted to him for a certain share of its usefulness and popularity, and for this we thank him. But the truth is, the Doctor has long been the pet of the Lancet, and is as sensitive and easily offended as a spoilt child. We have already sacrificed much to satisfy him with regard to his Lectures—a complete course of which was laid aside after we had incurred the expense of having it taken down; we have been obliged to act in contradiction to our promises to our readers, by his arbitrary and unaccommodating interference, after he had given us a *carte blanche* to do with his lectures as we chose. We were most anxious to keep faith with our readers, and to go on with the lectures without him; and we did not understand that yielding to his wishes, against our own interest, by postponing the publication to suit his convenience in correcting the press, was to be considered as a tacit engagement not to criticise any thing he did, or even to point out the grossest mistakes into which he might fall on other subjects; had we viewed it in this light, we should not for one moment have dreamt of complying with such terms.

We cannot sacrifice the independence of our journal, or offer up the kind of incense so liberally bestowed by our contemporary upon the idol of the day —now Lawrence, now Wardrop, and now Elliotson, to be lauded to the echo, while it serves the purpose of the editor, and then cast into oblivion as profound as if they had ceased to exist. We respect Dr. Elliotson's attainments; but to have passed over, without any notice, the mistaken view which he took of the other medical schools, and to have made no allusion to the tone of grandiloquence which he has assumed on several recent public occasions, would have been to abandon one of the legitimate and most useful purposes of our journal;—and we submit, that in exercising so difficult and ungracious a task towards Dr. Elliotson, we neither did it prematurely nor harshly.

To the fair and legitimate objects of the London University, we have, in repeated articles, proved ourselves no luke-warm friends;—to what we regard as a system of puffing and putting forth unfounded claims, we are, and shall continue to be, determined but not uncandid opponents. To those hostile to the institution, indeed, nothing could be more calculated to afford gratification than the measureless imprudence on the part of the learned Professor of Medicine, in carrying his dispute with any periodical, however influ ntial, into his class-room. The narrow escape from entire ruin which the school had but two years ago, in consequence of suffering affairs not connected with their proper business to be discussed by the pupils in the medical theatre, ought to have b en sufficient to guard even the most irritated against such an indiscretion We are the less disposed, however, to dwell upon it, because, from the steps already taken by the medical professors, we have reason to believe that there is little risk of its repetition. It speaks strongly in favour of our view of the matter, for us to be able to state, that the "Faculty of Medicine" at the London University have come to the determination that henceforth no opening "address" shall be permitted to be delivered until it has been laid before them, in order that the nature of its contents may be previously ascertained.

In conclusion, we would not be understood to allow the claim of any of our medical schools, as at present arranged, to unqualified commendation; and were it otherwise, we protest against the principle of hyperbolical eulogy and gratulation, as injurious to those to whom it is addressed—not stimulating them to exertion by the honourable motive of a generous emulation, but rather encouraging the busy vulgar to become conceited, and leading the indolent arrogantly to repose in an assumed superiority.

DR. ELLIOTSON'S LECTURES.

As Dr. Elliotson, in the letter which is given in a preceding page, has intimated a wish that we should discontinue the publication of his Lectures; as he has implied that he has been unhandsomely treated with regard to them, and has expressly stated that he "repeatedly entreated" us not to publish them, we feel called upon to enter into the following plain statement of the facts.

In Aug. 1830, the Doctor's permission was asked for the publication of his course, to be begun in the October following. Here is his reply:—

"Dr. Elliotson presents his compliments to the Editor of the Medical Gazette, and while he feels much flattered by the desire expressed, fears that his lectures are even yet too imperfect to be either very creditable to himself or useful to any publication.

"As, however, he never objects to the publication of any lecture or public case of his own, *he trusts the Editor will use his own pleasure, without considering it at all necessary to enter into any terms upon the subject.*

"He regrets to say that his MS. ex-

tends only to three-fifths of his lectures at present, and even to that extent is merely notes, and written too badly to be legible to any one but himself."

The lectures were in consequence advertised, and a most able short-hand writer employed to report them, at two guineas per lecture. Dr. Elliotson, however, having expressed a strong desire that their publication should be delayed, in order to afford him time to improve them, they were abruptly discontinued, after only one had appeared; but from an understanding (which subsequently proved to be ill-founded) that Dr. Elliotson purposed to correct and amend those very lectures, at his leisure, the short-hand writer continued his office, and took down the entire course, amounting to sixty-eight lectures. It is to this course alone that Dr. Elliotson can by possibility refer, as having "repeatedly entreated" us not to publish it; and in doing so, he has forgotten to add, both that his request was complied with, and complied with at a very considerable pecuniary sacrifice.

Last year, before the commencement of his course, an application was made to Dr. Elliotson on the subject of the lectures which had been taken down the previous season. Upon this Dr. Elliotson declared that he had never intended to correct those lectures for publication. Finding that some misconception had occurred with regard to the course reported, (for this we do not throw any blame on Dr. Elliotson, further than for having in the first instance given his unconditional assent,) we wrote to Dr. E., to ask whether, if we had his lectures taken over again, (meaning the course he was then about to deliver,) he would have any objection to their being published; and if he had not, whether he would choose to correct the press. He immediately gave his consent to the former proposition, but declined looking over the proofs, implying that it was not necessary; for he went on to state that he had corrected the proofs of his *clinical* lectures, "knowing in how slovenly a way he was obliged to deliver those (the clinical) lectures, from want of preparation." The note, however, in which Dr. E. declined correcting the press, was followed next day by the subjoined:—

"Dr. Elliotson presents his compliments to the Editor and Proprietors of the London Medical Gazette, and, as it is impossible for him not to acknowledge the high compliment paid to him by their incurring the expense of a short-hand writer for his present long course of lectures, and, as he feels it right to express his regret equally with those gentlemen that the slightest difference should have occurred, he begs to say that he will correct the press if but one lecture is published a week, and the proofs (not the MS.) are sent him on Fridays, and allowed to remain with him till the Monday."

Thus, then, the publication of Dr. Elliotson's course proceeded. Well; the summer came; when what was our surprise and annoyance to find that, notwithstanding our repeated announcements of our purpose of continuing the lectures without interruption to the conclusion, and notwithstanding the rigid fulfilment of our part of the above contract, we were forced in the most unceremonious and unexpected manner to suspend their publication. Dr. Elliotson now stated his desire that the course should be divided into three parts, one of which was to be begun each October, *during three successive years*,—thus extending his lectures into six volumes of the Gazette!! We earnestly remonstrated against the discontinuance of the lectures, but were cut short by the following peremptory refusal:—

—— "The Editor must (may) follow his own inclinations; but Dr. Elliotson has made up his mind to correct no more till October."

We then stated that we were committed to the public, and should go on with the lectures, without troubling him with the proof-sheets; upon which Dr. E. intimated his determination, if we did so, to take every means of stating that they were incorrect: nay, regardless of the pecuniary sacrifice we had made with respect to the first course, that the lectures might not be published in a form which he disliked—and heedless of the further and very large sum expended on the reports of his extended course, taken afresh last winter—he went so far as to threaten that he would announce that he intended to publish the lectures himself. We were weak enough to listen to this; and, anxious as we were to keep faith with the public, and doubly anxious though we were to go on, now that we were fully acquainted with

the system of "correction" applied to the lectures, we yet agreed to suspend the publication till October rather than suffer an open and violent explosion to take place on the part of Dr. Elliotson. We therefore inserted in the Gazette a notice praying the indulgence of our readers for the step which we had taken, and without imputing the least blame to Dr. Elliotson. Our correspondence was then wound up with the following polite note from that gentleman, in allusion to the announcement which we finally made:—

"Dr. Elliotson begs to express his best thanks for the gentlemanlike course adopted by the Editor of the Medical Gazette, in regard to the notice to subscribers."

So much for the facts.

DEATH OF PROFESSOR SCARPA.

One more is added to the number of illustrious men who have been taken from us in the course of the present year. Antonio Scarpa died at Pavia, on the 31st ultimo, of a disease of the bladder, in the 86th year of his age. During his illness, he received every attention from his numerous medical friends, some of whom had formerly been his pupils. This eminent professor was called to the chair of Anatomy at the early age of twenty-two; so that he held the appointment during the extraordinary period of sixty-three years!

ASSASSINATION OF M. DELPECH.

This deplorable event, which took place at Montpellier on the 29th ult., has created the most intense and painful interest relative to the facts. Demptos, the murderer, had been a patient of M. Delpech's some time before: he was treated for varicocele, and it would seem that the cure was attended with circumstances that rendered it imprudent for him to form a matrimonial engagement. It is further stated, that M. Delpech having been consulted by a family into which Demptos wished to marry, gave them some intimation of his patient's condition: Demptos met M. D. at the theatre the night before the fatal deed, and it is thought that he demanded from M. Delpech a retractation of what had been said to the family. However, on the 29th, the assassin stationed himself in the balcony of the house where he lodged, and watched the approach of M. Delpech's cabriolet. It came: when with one shot from a double-barrelled gun he killed the servant, and with the other the master. He then retired into the house, and blew out his own brains with a pistol. M. Delpech expired in a few minutes. His obsequies were performed on the 31st, amid the general lamentation of the people of Montpellier. Orations were pronounced over his tomb by MM. Duges, Boyer, and Trinquier.

M. Delpech was in his sixtieth year. He was a chevalier of the legion of honour, professor of clinical surgery to the faculty of Montpellier, surgeon-in-chief to the principal hospital, and a member of numerous learned societies throughout Europe.

On examination of his body, it was found that the ball had entered just above the nipple of the left breast: after fracturing a rib, it passed through the upper part of the lung, tore the cross of the aorta, divided the apex of the right lung, and came out at the shoulder of that side, after a fracture of the humerus. From morbid appearances discovered in the lungs, it is supposed that M. Delpech could not, in the ordinary course of nature, have lived many years.

ST. GEORGE'S HOSPITAL.

Contusion—Hysteria, simulating severe Injury.

Ellen Sedgwick, æt. 26, married, admitted Sept. 23, 1832. She fell from a quay, from a height of several feet, upon the gravel bed of the river below. The accident occurred about 9 P.M. and she was brought to the hospital about half-past one, screaming and wholly insensible, and unable to stand, and making so much noise, apparently from violent pain, as to alarm the whole house. From her manner, it was at first supposed she must have injured the spine; a great deal of contusion being also perceived upon the left side, along the hip and about the shoulder. She recovered her senses in some measure when left quiet in bed.

24th.—She has continued to have the appearance of suffering extreme pain; her countenance being pale and expressive of great anxiety, and her hair and cap thrown about and disheveled. She is constantly turning in bed, apparently from pain, and is half insensible; lying with her eyes shut, and with difficulty roused to answer ques-

tions in a half whisper. She has incessant vomiting of dark-green fluid, which is sometimes mixed with blood, and she shrinks upon being examined about the injured parts, or on the abdomen, as if there was excessive tenderness. She is able to move her legs, but has made no water since the accident, and, in fact, passed none for twenty-eight hours.

All this looked sufficiently alarming, and might easily be supposed to have been connected with severe injury; but, upon examination, it became quite clear that her real injury was trifling contusion only of the side, and that she was suffering from hysteria; for it was found, on inquiry, that she had been subject to a variety of hysterical symptoms—that she often had pain in the side and spitting of blood, and there was habitually an excited state of the uterine functions. In fact, she was only just recovering from what had been considered as a severe illness, for which bleeding and antiphlogistic means had been employed pretty largely, and she had been repeatedly bled for the hæmoptysis, as in former similar attacks. The patient had been dining out for the first time since her illness, and had probably indulged in good things enough to produce all her bilious vomiting.

Accordingly the sickness and all her other symptoms quickly subsided by the use of a smart purgative, &c. and she left the hospital in a few days, with only a little stiffness from her bruises; receiving, however, a caution from Mr. Hawkins, not to be so fond of bleeding for the future, when the hysterical pain or hæmoptysis should occur.

MEDICO-CHIRURGICAL SOCIETY.

Tuesday, Nov. 13, 1832.

W. Lawrence, Esq. in the Chair.

This, which was the first meeting of the season, was very numerously attended. The Secretary read a paper from the pen of Dr. Bright, entitled "*Cases and Observations connected with Diseases of the Pancreas and Duodenum.*"

The chief object of the author, in this paper, was to direct the attention of the Society to the consideration of a peculiar matter of the nature of adipocere, which occasionally passes from the intestines; and, without wishing to assert that there was any necessary connexion between this symptom and disease of the pancreas or duodenum, he shewed that a scirrhous state of the head of the pancreas, and fungoid ulceration of the duodenum, had existed in the only three cases in which an opportunity had been afforded him of examination after death. He, however, at the same time adduced some other cases, where similar states of disease, though not precisely the same, had been found in these parts; and in which no such fatty evacuation had been observed. He offered it, therefore, as a question, whether this peculiar substance were to be considered as a vitiated secretion from natural structures, or as a discharge from the diseased and ulcerated parts; or as the product of the defective digestion of alimentary matter, depending on the imperfect supply or irregular admixture of the biliary and pancreatic or other secretions, or the perverted and impeded action of the duodenum?

The paper concluded with a few general remarks on the diagnosis in diseases of the pancreas, accompanied with an observation, that it appeared possible the fatty excretion of which he had been speaking might prove rather an indication of the morbid action attendant upon the carcinomatous state, than a diagnostic mark of the organ affected.

LECTURES

ON THE

THEORY AND PRACTICE OF MEDICINE;

Delivered at the London University,

By Dr. Elliotson.

CUTANEOUS DISEASES.

PUSTULÆ.

We now proceed to another order, in which the secretion that takes place under the cuticle is pus. Now you will find in this order several very important diseases: there is one, for the most part of a chronic nature—*impetigo*; there is another, like that I have just spoken of, only it is contagious—*porrigo*; then there is another, called *ecthyma*; and there are also *cow-pock*, *chicken-pock*, and *small-pox*. Thus you see that, except in the formation of pus, there is no agreement among these diseases: some are acute, and some are chronic; some are simple diseases, and some are contagious; some of these contagions diseases occur but once during life, and others occur frequently. Porrigo may occur over and over again; but small-pox, as a general rule, does not occur more than once.

Impetigo.

The first disease of the order pustulæ, of which I will speak, is called *impetigo*. I speak of it first, because it is closely connected with eczema. Eczema, which is for the most part a chronic disease, is characterized by small watery vesicles, and frequently has, instead of clear lymph, a fluid almost puriform; sometimes it is altogether puriform; and, in this latter case, we call it impetigo. The two diseases run completely into each other. Neither eczema nor impetigo are in the least contagious: you may touch a person labouring under them, or inoculate with the fluid, and no disease will arise from it; at least nothing more than irritation.

Species.—This disease will occur sometimes in circumscribed patches, just as you see in the case of herpes, and then it is called *I. figurata*; and frequently there is an inflammation around, just as in herpes. Now and then the affection is extended very much over the surface, and is called *I. sparsa*. Now and then there is a thick scab, and then it is called *I. scabida*. The affected part looks like the bark of a tree, only that you see it is not diseased cuticle, but a real scab formed of dry pus. Now and then there is so much inflammation around that it is called *I. erysipelatodes*. Now and then there is such irritation that it is denominated *I. rodens*. It is only worth while to remember that it may occur in clusters; that it may occur with scabs, with a great deal of inflammation, and with ulceration: I would not have you trouble yourselves about the particular expressions. Now and then, I mentioned that the fluid is here and there watery, not purulent, and then it is called *eczema impetiginodes*; and if you choose, because there is pus in other parts, you will be justified in calling it *impetigo eczematodes*. These are the same diseases, only according to the severity of the irritation you will have pus or water.

Varieties of Pustules.—Now it is right you should know before we speak more of pustular diseases, that pustules are divided into four kinds, according to their size and figure. If a pustule be conically pointed and small, it is called *achor*; if on the other hand it be small, but flat, it is called *psydracium*; if it be larger, and have a sort of honeycomb appearance, it is called *favus*; but if it be a fat, large, well fed pustule, with an inflammatory base around, it is called *phlyzacium*.

Now in the disease that I am speaking of, the pustules are small, just as the vesicles are small in herpes: they are of that kind which are called psydracia. It is of some use to remember this variety of pustules, because one disease has one species of pustule, and another a different kind. When the itch has pustules, they are of that description called phlyzacia. [The lecturer illustrated the appearance of the various kinds of pustules by a reference to the title-plate of Dr. Bateman's work on Cutaneous Diseases.] The names given to these pustules are very hard words, and it would have been well had some others been devised, but we must suffer through our forefathers. It is of use to remember the appearance of the pustules in this disease, because in porrigo it is sometimes difficult to distinguish them from these, and the difference in the pustules is the principal means of diagnosis.

This disease, which is easily recognized, on account of its being a pustular affection, and being characterized by the formation of pus in small flat pustules, occurs particularly on the extremities. You will continually see both men and women with this disease on the front of their legs, sometimes running all around, and sometimes upon the arm. If it be not properly treated, it will sometimes last for a very considerable time. Sometimes there is a great degree of inflammation attending it—a great degree of heat and smarting, and yet the patient, although he may be married, and consequently have a bed-fellow, does not communicate the disease to his wife. It will last month after month, and sometimes even for years.

Treatment.—The best mode of treating the disease, and the one that I have adopted, has been to regard it as an inflammation—taking blood from the arm, applying leeches around the inflamed part, applying cold water as long as that was agreeable, and then exchanging it for warm, and exhibiting mercury. This is an affection in which I am sure that a moderate use of mercury is necessary. All this, however, will be of no use, if the patient do not limit his diet. If you do not cut off wine and beer, and in some cases meat, you will not find the disease go away. It is a disease which is exceedingly obstinate, if it be not well treated. If you adopt the plan I have laid down, although you may not eradicate the disease, yet you will lessen it to a very great degree. The chlorides are sometimes useful, and likewise the yellow wash, but frequently I have seen them irritate the part, and, altogether, the best local treatment is the application of some absorbent powder, such as calamine or oxyde of zinc, and the constant application of cold or warm water. In the case of the leg, it is indispensably necessary that the patient should keep it as much as possible in a recumbent posture; just as he would do in any other inflammation of the lower parts of the body. In the way of medicine, I am quite sure that mercury, exhibited very gently, is exceedingly serviceable.

In that form of the disease which is the link between impetigo and eczema, the treatment would be precisely the same. You will frequently see eczema of this kind behind the ears, running over the face and down the neck — sometimes attended with a discharge of water, and sometimes with a discharge of pus: in fact, it may be either eczema or impetigo. When there is merely eczema, you have a great deal of scurf upon the part, so that when the secretion is stopped the patient looks almost well; and then, when the part begins to run again, you have the neck looking moist and nasty, and quite a different appearance. Whether it is eczema or impetigo, I believe antiphlogistic treatment, with the moderate exhibition of mercury, and the application of an absorbent powder, answers far better than any thing else.

Impetigo cannot be mistaken for any thing else except eczema, and they run very much into each other.

It is a common disease; you cannot go into a hospital without seeing cases of it. You might almost as well give different names to rheumatism, if it ran down one shoulder, or occurred in both shoulders, or in one shoulder and one knee, as give different names to many of these cutaneous affections. It is very well to mention that they may occur in this way or that way, but to give them distinct names is quite absurd. In plate xxxviii. of Bateman, you will see a representation of the disease called porrigo, which is nothing more than eczema; and the same may be said of the representation of psoriasis in plate ix. fig. 2. If there be a watery discharge it is called eczema; if it be matter it is called porrigo. Psoriasis, eczema, and porrigo, run into each other.

Ecthyma.

I now proceed to speak of another disease which also is not contagious, and is characterized by pustules called *phlyzacia*, the large, round, well-fed pustules, with an inflamed base; this is a disease which very frequently takes place in a bad habit of body. The disease which I last spoke of (impetigo), takes place occasionally in a cachectic state of the system, but frequently it takes place in persons who are in other respects very well. The disease which I now speak of, ecthyma, is one which commonly occurs after smallpox, measles, and scarlet fever, and now

and then after syphilis; occasionally, I believe, it is itself syphilitic. It is characterized by pustules which are all distinct. In impetigo the pustules cluster; and when they are aggregated they sometimes form clumps or clusters, and now and then they occur over a great extent, so that sometimes you have clumps, if I may so speak, and sometimes diffused patches; but in ecthyma, of which I am now going to speak, the pustules are all pretty distinct, and sometimes very large. You will at once see by the plates the difference between this disease and that of which I spoke last. If you were to look at a patient, without knowing any thing of his history, you might think that he had the small-pox. You will continually see this affection in patients in the venereal wards, it having come on in consequence of taking mercury. The pustules, you observe, are all distinct and round; they are large, circular, and full of matter; not flat on the top, but globular. I have seen cases exactly like small-pox; and indeed I once knew a case sent to the hospital for small-pox, merely in consequence of the resemblance of the pustules. Now and then you have the pustules remarkably large. When I say they are full, I mean they are distended. Whether they be large or not, the discharge concretes into a dark-coloured scab. I recollect having had this disease when a child; for I have had a taste of most diseases. I remember being very scabby for many months, so that I was quite ashamed to be taken out for a walk. It is a disease which lasts a considerable time. Persons who say they have merely had gonorrhœa frequently have an eruption exactly of this description. It is very easily recognized; in the first place you see that there are pustules, therefore the affection belongs to the order pustulæ; you also see that they are phlyzacia, that all of them are distinct, and that some of them run into scabs. For the most part they are not very numerous, but when they are small they may be so. In impetigo they are circular, and not so distended, and have little flat tops. Sometimes, in impetigo, they will congregate into one large mass; but in ecthyma the scabs are all distinct, though they may be large.

Varieties.—One of the varieties of this disease is called *E. vulgare*, and it certainly gives a person a very vulgar appearance; but if it be a little darker, it is called *E. lavidum.* (If lepra be dark, it is called *L. nigricans*; and it is a pity that the same adjective is not employed here.) If it occur in children, it is called *E. infantile.* We might as well apply a separate epithet to measles, accordingly as the affection occurred in infants or adults; but you see that this fondness for subdivision runs throughout Willan's arrangement. I mentioned that the disease generally occurs in a bad habit of body; and if it take place in a very bad habit, it is called *E. cachecticum.*

It will now and then occur (and you will recollect that this is the case with almost all cutaneous diseases,) with a sharp inflammation, and may last for a short time, just like herpes, or some other inflammations which produce mere serum, or which cause no secretion at all, but constitute a mere redness. They begin with inflammation of the skin, and feverishness; but the result of this disease will be suppuration. For the most part, however, ecthyma is a chronic affection, and lasts a considerable time, the patient being very much out of health.

Treatment.—Under these circumstances, the most eligible treatment is to strengthen the patient in the best mode you can. Allow him wine, porter, meat, and fresh air, every day, and the warm bath; and if there be strength enough, I know that the employment of the cold bath is very good. I would use the cold shower bath in cutaneous diseases, when the patient's strength was able to bear it. Very frequently the disease is syphilitic; and although the body is feeble, you find it necessary to give mercury, as well as to employ tonic medicines. Because you give mercury, it is no reason why you should not strengthen the patient as much as you can. It is frequently a good practice to allow wine, porter, and meat in abundance, and give tonics—wine and bark—while you employ mercury. Sometimes you may alternate them.

Rupia.

There is a disease very much like ecthyma, and indeed it appears to me to be exactly the same; but it is placed by Bateman in the order vesiculæ, merely because the disease is serous instead of pustular; and Rayer places it, because the vesicles are large, in the order bullæ. They occur under the same circumstances, the secretion soon becomes purulent, and, after a time, there are the same large black scabs; and no one could then tell whether the disease was rupia or not. For the sake of consistency it may be necessary to make two diseases of these; but I am satisfied that rupia is nothing more than ecthyma—that ecthyma and rupia are varieties of the same affection. All I wish you to remember is, that ecthyma sometimes begins with serum, and that it soon becomes thick and turbid. There is another reason for making the two the same. In rupia there is frequently a scab,

which becomes conical, exactly the shape of those shell-fish which stick to the rocks, and that form of it is called *R. prominens.* Now in ecthyma there is frequently the same occurrence; the scab will assume exactly the same appearance; and the treatment of the two diseases is exactly the same. I cannot but think it trifling to separate them in this way. Although Rayer finds fault with Willan for subdividing these affections, yet he is over minute himself. However, I will shew you what is meant by rupia (exhibiting two plates). The affection will occur in little children, particularly if they have been thrown out of health by measles or small-pox; and sometimes it will even occur after cow-pock. You will observe that the vesicles are circular, with inflammation around, and they leave a black scab. They occur distinct too, just like the pustules of ecthyma, and you find they are globular, only that the contents are watery. Where the disease has been purulent from the beginning, I have seen dark scabs. Rupia, too, is as frequently syphilitic as ecthyma, and just as frequently requires mercury.

Treatment.—When this affection occurs in adults, they require support; and now and then you will have to give mercury. With respect to local applications, I have never seen them do any good. You should keep the parts clean; and when the scales come off, it is well to use a dressing of oxide of zinc, or ung. hydrargyri.

I would put ecthyma and rupia together, just as I would put lichen and strophulus, erythema and roseola; and just as I mentioned, I would make no distinction between the order of vesiculæ and bullæ. I would make some one word to signify all the diseases, from the size of a millet-seed to that of a hen's egg. There is a man in St. Thomas's Hospital now, with a syphilitic complaint, who has one of these pustules on his arm. It is a very common affection.

Varieties.—There are two kinds of rupia—*R. simplex* and *R. prominens*; but it is quite enough to recollect the word rupia.

Porrigo.

The next disease that I will mention, and which is also a chronic affection, is, however, of a contagious character. The two preceding diseases, impetigo and ecthyma, together with rupia, are perfectly free from contagion; but there is another, a chronic disease, which occurs particularly in the head, called *porrigo*, which is exceedingly contagious.

In porrigo the pustules are different from what they are in those other two diseases. In impetigo they are little pustules, and flat; in ecthyma they are large globular pustules—phlyzacia; but in porrigo, or scald head, they are small, with pointed tops, or large and flat—that is, they are either favi or acores. If you look at the scald head of a child, when there are pustules, you will find them exceedingly small, with pointed tops—therefore they are acores; or large and flat—therefore they are favi.

The disease is only contagious, not infectious. It is commonly caught by children sleeping in the same bed, rubbing their heads upon the same pillow, or wearing the same night-cap. Frequently it is caught at school, by children putting on each other's hats or caps. I have no doubt that many diseases which occur in the head are called porrigo that are not. I think I have seen enough to justify the opinion that many cases of eczema are called porrigo. But this disease, though it usually affects the head, may occur in various parts of the body: however, the head is by far the most common seat of it.

Varieties.—It sometimes occurs in distinct patches—studs of it—and it is then called *P. scutulata.* Now and then it occurs with a great deal of inflammation, and in distinct pustules, not clustering together so much; and these being favi, it is called *P. favosa.* Sometimes it has dry laminated scabs, of a yellow-whitish colour, containing a white sealy powder; and, from their resemblance to lupin-seeds, it has been called *P. lupinosa.* In this form of the affection the pustules are often very dry; the patches are full of hard grains, which are found to contain a great deal of lime; an earthy secretion takes place. You will see the representation of the common form in this plate (exhibiting it). They are not little globular pustules, but large and flat, and therefore they are called favi. When you see an eruption occurring in the head, of a pustular kind, lasting some time, you may be almost sure it is porrigo; but if you ascertain that there are small pustules (acores), or that they are large and flat (favi), then you may be sure of the nature of the disease. It is said to occur in other parts of the body, but I do not recollect seeing it. Impetigo, eczema, and ecthyma, are common enough on the extremities; but porrigo is much more particularly found on the head. It is one of the most contagious of cutaneous diseases. Drinking out of the same mug, or giving a kiss (if any one could be tempted to do so), I should think would communicate the disease. If a man had been married to such a female as this (exhibiting a plate) for twenty years, and his wife was very ill, certainly he might be tempted to give her a kiss; but not otherwise.

Duration.—Porrigo takes place far more frequently in children than in others; and it very often cures itself, when it is thought to be cured by medical means. It lasts for a certain time, and gradually declines. Children have it for a great number of years, and then as they grow older it ceases. There are diseases which are common to infancy, which gradually disappear as the subjects of them grow older, and scald head is one of them; but I have seen persons labouring under it who had attained their 20th or 25th year, and who said that they had had it all their lives.

You find a variety mentioned by Bateman under the name of *P. furfurans*, where there are no pustules, but you find there laminated scabs. I believe this is nothing more than eczema, and I do not think it at all contagious.

Treatment.—Now as to the treatment of this disease, it is one of the most obstinate that you can take in hand. You often find great inflammation, so that on approaching your hand to the patient's head you will feel great heat, and you should certainly premise your treatment by antiphlogistic measures, by taking blood from the neighbourhood of the head, and by applying cold water. These things are certainly useful, and they appear to be indicated by common sense; but they are only useful to a limited extent, and you will, as I just now said, find the affection very obstinate. It is sometimes of great service to give mercury. I may mention that Plummer's pill first obtained its credit by curing a disease of this description. Dr. Plummer, Sen. of Edinburgh, states in the Edinburgh Essays, that he had a case of scald head, for which he gave some common form of mercury, but the patient was no better. He then gave it mixed with a little guaiacum and antimony, and the patient presently got well. This pill was much employed by him afterwards, and others also used it, till at last it became well established, and *Plummer's* pill is now as well known as *Dover's* powders. I much doubt whether it has any efficacy beyond an equal proportion of calomel; at any rate I do not think that a grain of guaiacum can make any difference in a pill; and as to antimony, I believe, unless it produces nausea, it is not worth the name of medicine. I have made comparative trials with calomel and Plummer's pill, and I can say that I never found the latter at all superior to the former. I think it impossible to conceive that a grain of guaiacum can make itself known in the constitution. However, mercury is often useful, and also sarsaparilla, and things of that description.

As to external remedies, besides antiphlogistic measures, astringents are very useful—oxide of zinc and calamine. If there be but little inflammation, you find tar ointment, united with that of nitrate of mercury, serviceable; and sometimes an ointment of the red oxide of mercury. These stimulating applications are often exceedingly useful. I have seen cases get well under the use of cocculus indicus. It is used to destroy vermin in the heads of children; and if you put a drachm to an ounce of grease, you have a stimulating ointment, which is often beneficial. Sulphur, too, has been employed: a wash of the sulphuret of potass is sometimes found advantageous in the disease. But among external applications, when there is no great inflammation present, tar and citrine ointment are among the best. I need scarcely say that the head should be closely shaved, and kept very clean.

Porrigo Decalvans.—Now this disease will sometimes occur without an eruption, so that we have an affection classed with those which are pustular, and in which, nevertheless, there are no pustules; but this inconsistency we cannot avoid. The hair will sometimes drop off here and there in patches, leaving the surface smooth; and this disease is said to be contagious. It is a very common affection, and is called *P. decalvans.* I believe it is very common in the West Indies, and I have seen it in children who have come from thence. It is said to spread in schools, just like the other forms of porrigo, from the children wearing each other's caps.

There is a doubt as to whether this should be called porrigo: the skin is smooth, and I am sure in many cases this is the entire disease. Here is baldness without any reference to pustules, or vesicles, or an inflammatory affection. Sometimes half the head will be bared in this way, and sometimes the whole head. I had a little patient last year whose head was becoming perfectly smooth all over: I could do nothing with her. (The case is described in the Medical Gazette, vol. vii. p. 639.)

Treatment.—Stimulating applications are among the best. I should recommend you to use red oxide of mercury, and others of a similar description; in fact, treat it as you would do the other forms of porrigo. You must keep the head well shaved all round, and very clean, and by applying stimulating applications the hair will at last come on. It is said that there is no doubt as to its being contagious, but I have not seen it so. It is by no means uncommon; but like the other forms of porrigo, it will cease after a time.

I need not say that in the various other forms of porrigo, when there is a scab, in order to employ the ointment with effect,

you should put plenty on; and when you have softened the scabs, you must have them taken off. You should, however, have them softened as much as possible at first, and for this purpose a poultice is sometimes necessary.

To shew you how very contagious these diseases are, I may mention that I recollect a barber who had a child with a scald head, and he kept a razor specially for shaving it. One day by mistake he shaved himself with it, and although he had washed and stropped the razor well, and like a true barber put it into hot water first, yet in consequence of using it to his own beard, the disease came out upon his chin about a week afterwards. I saw it distinctly, and he told me the history of the case. Small circular pustules came out.

You cannot too strongly impress upon the minds of people, the necessity of a child's dress being kept isolated in this affection, lest the disease should spread.

These, gentlemen, may be said to be all the chronic pustular diseases; and those which I mean next to speak of are acute, and occur but once during life. They are diseases which we see every day; namely, chicken-pock, cow-pock, and small-pox. It is now believed by a great many, that the two latter of these affections are one and the same; and some go farther, and think that even the chicken-pock is only a modified form of it. However that may be, these diseases are all exceedingly similar, so far as they are pustular, so far as they are all highly contagious, so far as they are acute diseases, and for the most part occur but once during life. I believe, however, as the hour is nearly expired, it will be better to begin the consideration of these at the next lecture, because the particulars of these various diseases are so numerous, that confusion will arise from descanting on too many at once.

LECTURES

ON

DISEASES OF THE EYE;

Delivered at the Birmingham Eye Infirmary,

By Richard Middlemore, Esq.

DISEASES OF THE CONJUNCTIVA, CONNECTED WITH CONSTITUTIONAL DISTURBANCES.

It will be necessary for you to investigate most particularly the circumstances of each individual case, if you mean to practise your profession with correct views and with a due share of reputation. You will sometimes find that an obvious disorder of the digestive organs is the cause of the continuance of inflammation; and if you attend to the diet and habits of the patient, and keep the bowels properly acting, by the use of blue pill and colocynth, or some suitable purgative medicine, you will have the satisfaction of finding an improvement in the state of the eye along with that of the alimentary canal; in short, the cure will be completed without the aid of any local application whatever. You may perhaps discover, in your investigation of a case, that the attack immediately succeeded the healing of an ulcer to which the patient had been subject for many years, and you will not fail to take advantage of this discovery, by placing an issue in the arm, or substituting some more eligible mode of employing counter-irritation, or more desirable situation for that purpose.

If a patient were to present himself to your notice with acute inflammation of the conjunctiva, and you found him of a full plethoric habit, and if he were to tell you that he was in the habit of living after the reputed habit of our city aldermen; and if, on inquiry, you discovered that he was subject to such attacks, and that occasionally, after any unusual exertion, the vessels of the conjunctiva gave way, or, to use the familar phrase, "the eyes became bloodshot;" you would at once see the propriety of warning him of the danger such a state of things pointed out, and of the necessity of lowering the general fulness of the habit, as a measure not only necessary for the subduction of the inflammation of the eye, but also as one absolutely required, in order to place him out of the very imminent danger of suffering from an attack of apoplexy, or rupture of blood-vessels in some important situation.

Presence of hydatids, tumors, &c.

In alluding to the causes of inflammation of the conjunctiva, I mentioned tumors at the edges of the eye-lids, an inverted state of the tarsal cartilage, inversion of the eye-lashes, growths from beneath the conjunctiva, &c. Now should this inflammation appear to arise from, and be maintained by, a small tumor at the edge of the eye-lid, it must be extirpated as soon as the acute symptoms have been somewhat subdued by the remedies previously mentioned; if from inversion of the border of the tarsal cartilage, the operation to be afterwards described must be had recourse to, for the purpose of correcting this defect; if from an inverted position of only one or two of the ciliæ, which is not rectified after they have been several times extracted, their bulbs must be dissected out; or if there be a general

inversion of the eye-lashes, the edge of the tarsus containing the whole of the cavities for the bulbs of the ciliæ must be removed by an incision throughout its whole length, taking care, of course, not to injure the punctum. If the inflammation of the conjunctiva be occasioned by growths from its surface, they must be cut away; or if from tumors beneath it, they also must be excised. I remember examining the eye of a lady who had frequently suffered from relapses of inflammation of the conjunctiva, and on discovering a small elevation of that membrane near to the cornea, I divided it along the most prominent part of its surface, and there immediately escaped a small hydatid; the wound soon healed, produced no injurious cicatrix, and the operation afforded the patient an immunity from these annoying attacks of inflammation, to which, from this cause, she had been previously very subject.

Irritation from the presence of foreign bodies—Removal.

It would be drawing too largely on your time to enumerate all the cases of a like kind it has fallen to my lot to witness: I shall content myself, therefore, with thus directing your attention to the multifarious sources of mechanical irritation, of which the eye is so acutely susceptible, from the peculiar, though necessary, delicacy of its organization. I must, however, request your attention, for a few moments, to a description of the various modes of removing one frequent source of irritation; namely, the presence of foreign bodies upon, within, or beneath the conjunctiva. Sometimes persons will call upon you in extreme torture, in consequence of a minute particle of sand, dust, or metal, having been suddenly insinuated beneath the lids, or, as it is popularly termed, "getting into the eye:" and, if you ask them to open the eye, they will tell you the attempt occasions an intense degree of anguish: this is not, however, always the case, for, in some instances, foreign substances remain within or beneath the conjunctiva without appearing to provoke any uneasy feeling. They may derive an adventitious covering, or be covered with the smooth conjunctiva, and thus be prevented from giving rise to any irritation; but, generally speaking, they produce considerable pain and irritation, until they are removed by art, or become detached by the process of sloughing. The friction of a delicately smooth and highly susceptible membrane, not naturally possessing the slightest inequality of surface, but most accurately adapted to the size and figure of the part upon which it is intended to move, upon a sharp angular body, must be supposed to occasion great suffering,—a suffering, however, of a salutary nature, inasmuch as it excites attention to its removal, by which those evil consequences—those disorganizing actions attending its long continued presence, are prevented from taking place.

The irritating substance, whatever may be its nature, will almost always be extremely minute, and it is generally situated at the reflected portion of the conjunctiva—that part of it where it passes from the lid to be reflected upon the globe. Now you will not find it, when so situated, by merely separating the eye-lids with the fingers; it will be necessary, in order to obtain a view of it sufficiently distinct to enable you to remove it, to evert the upper eye-lid: for this purpose you draw down the skin of the superior palpebra, pass a probe along the frontal margin of the tarsal cartilage, and then suddenly turn it upwards upon the probe, by means of the eye-lashes and surrounding integuments. You thus expose the whole under surface of the upper eye-lid, and obtain a clear view of any substance which may be lodged beneath it. If it be not impacted in the loose membrane, it will be generally washed towards the inner canthus by the elevation of the part which confined it, and the profuse lachrymal secretion, which, under such circumstances, always takes place: should this not happen, it may be readily detached by the grooved end of the curvette, or any similarly formed instrument. However, before you have recourse to the eversion of the lid, it would be right to examine the eye very carefully; for it is possible that the irritating substance may be lodged at any other part of its surface: for this purpose you would separate the lids as widely as possible, and carefully inspect the surface of the eye. Having done this, you may direct the patient to look first upwards, then downwards, and to either side, and if by these means you do not detect the object of your research, you would of course adopt the method previously mentioned: you would evert the upper eye-lid.

We will now suppose that a sharp fragment of metal, or some hard angular substance, has been forced into the conjunctiva, and may be seen projecting from it; or, having transfixed that membrane, has passed beneath it, at a distance from the point at which it entered. In the first of these supposed cases, you would, without hesitation, grasp it with a pair of forceps, and extract it, or raise it from its situation by the aid of some moderately pointed instrument; or, if this could not be readily accomplished, in consequence of the contraction of the conjunctiva around the foreign body, from the enlargement of the vessels, or the deposition of inflammatory

secretions, you would no doubt enlarge the opening in the conjunctiva, and then you would experience no difficulty in removing the foreign body. In the latter case—that is, where the foreign body has passed beneath the conjunctiva at a distance from the spot at which it entered—you would divide that membrane at the part where it was most raised by the foreign body, and withdraw it, as in the former case. But in many cases you would not judge this mode of procedure expedient, inasmuch as, when a foreign body is so situated, it will not generally, from the circumstance of its obtaining a smooth covering, produce much pain, but may cause the patient much suffering, and the operator much trouble to remove it, on account of the loose texture of the conjunctiva admitting of that extent of motion which causes any opening you may make in it to change its situation in relation to the foreign body; but, presuming the particle to be fixed in the cornea —to be merely imbedded in its substance, you would separate the lids, and having requested the patient to look in that direction which allows you to discern most distinctly the object you are desirous of removing, fix the eye by firmly pressing the finger on either side of it, (this is best accomplished by allowing the index and middle fingers to project beyond the tarsal margin of the lower eye-lid,) and raise the foreign body from its situation by means of some pointed instrument. But it may happen that the cornea is transfixed,—the foreign body has not merely divided its outer layers, but passed through its entire texture; you should not, in this case, think of removing it immediately, lest the iris should become prolapsed, the aqueous humour become discharged, and, as an almost necessary consequence, vision more or less seriously impaired: on the contrary, you must allow it to be discharged, or at all events loosened, by sloughing, thus permitting deposition to take place around that part of it directed towards the optic nerve, by which the opening in the cornea would be closed, and the evil consequences connected with the loss of the aqueous humour avoided. It often happens that after metallic substances have been removed, an appearance of their presence still remains, owing to the oxydation of a part of them, which has become adherent to the cornea. You will be careful to discriminate this appearance, and do not be solicitous to detach the brown spot of the cornea, for it will be almost always cleared away by a natural process, and any interference on your part will be absolutely useless, and may be very injurious.

There are many substances which exert a chemical influence upon the textures of the eye, and not only influence them, but alter their qualities; lime, or mortar, renders the conjunctiva pulpy, and the cornea densely opaque, and thus completely destroys vision; invariably, it may be said, when they are applied in large quantities, and permitted to remain in contact with them for any great length of time. If you were called to a case in which a quantity of mortar had been applied to the eye, soon after the accident had occurred, you would at once attempt the removal of every part of it, by means of a probe, or the blunt end of a curvette, and having done this, you would proceed to inject beneath the lids, so as to direct a forcible stream of it against the part to which the mortar is adherent, and this you would do so long as any appreciable portion of it remained: you would then drop a little sweet oil upon the surface of the eye; and lastly, employ the ordinary means for the prevention or subduction of inflammation, or for the removal of any other effects the injury may have caused. Unfortunately, when lime, in its concentrated state, or any other strong caustic substance, come in contact with the eye, they are so rapidly destructive in their effects that we have only to treat the inflammation they excite, with a view to prevent its extension to the parts behind, or to the opposite organ: in scarcely any instance can we preserve the sight of the eye, when substances of a strongly caustic nature have been allowed to remain in contact with its surface for any length of time.

The means, then, of subduing simple acute inflammation of the conjunctiva, or rather the principles to be acted upon with a view to effect this object, in cases where the inflammation is severe, and does not arise from any outward source of mechanical irritation, are, first, to lessen the general fulness of the system, and the power of the circulation; secondly, to diminish the vascular plenitude of the inflamed part; thirdly, to protect the eye from the influence of vivid light; fourthly, to rectify any disordered state of the health, and particularly any derangement of the alimentary canal, that may exist; fifthly, to employ counter-irritation in the neighbourhood of the disease; and sixthly, to remove heat by the local employment of various collyria, or relieve pain by means of anodyne and soothing applications.

Bloodletting.

It has been asked,—which is the best situation whence to abstract blood in such cases, and in what manner is it most desirable to remove it? We will endeavour to reply to these questions.

It was formerly the practice to bleed in

the foot, for the removal of inflammation situated at the upper part of the body, on the principle of revulsion; and many persons at the present day, who entertain an opinion that inflammation of the eyes frequently depends on suppressed discharges, are in the habit of harassing the part which has ceased to discharge as usual, on the supervention of ophthalmia, believing that to be, what they term, the most natural mode of cure. You will find such persons directing the application of leeches to the anus, if the eyes are inflamed, and an habitual hæmorrhoidal discharge is suspended; to the nose, if the customary epistaxis has ceased to be as frequent and considerable as usual; to the labia, if the menses are suppressed; and to the neighbourhood of old ulcers, if they have healed, or if the discharge from their surface has diminished in quantity. Such are the means employed by those surgeons who believe that the inflamed state of the eye depends on these various causes, and is best relieved by restoring the absent or deficient discharge, or by instituting some artificial drain from the part whence such discharge usually or naturally proceeds. If you act upon such pathological notions, do not let your attention be withdrawn from the at least equally necessary and more active part of the treatment.

Having stated that one of the chief points to be secured, in the treatment of acute ophthalmic inflammation, is to lessen the fulness of the vascular system, and diminish the power of the circulation, you will imagine that it cannot be of much importance, as regards the subduction of the disease, from what situation blood be removed for this purpose. There are, however, many reasons why bleeding in the arm is the more desirable mode of withdrawing blood, when we require a large quantity. If you open the jugular vein, you greatly annoy the patient by the constrained position in which it is necessary to place him during the operation, and until the bleeding orifice is closed; and frequently you cannot obtain the quantity it is desirable to procure. If you open the temporal artery, it is probable, also, you may be disappointed, or, on the contrary, you may find it difficult to restrain the hæmorrhage, unless you employ tight bandages, or some mode of compressing that vessel which will be incompatible to the feelings, and heating to the head of your patient; besides, it is remarked that after the temporal artery has been opened, for the relief of acute inflammation of the eye, the neighbouring arterial branches have assumed a hæmorrhagic action, such as is noticed in other situations after the current of blood has been suddenly and abruptly prevented from pursuing its direct course. There are circumstances which may render it advisable to abstract the quantity of blood you may require by means of cupping: for instance, a patient may be unusually fat, the veins in the arm may be extremely small and obscure, or, as is sometimes the case, he may have an insuperable objection to permit the opening of a vein: generally speaking, however, cupping is the best means of secondary bleeding —and, at a certain stage of the disease, combines, in its effects, the influence of depletion and counter-irritation. You will not discover many objections to bleeding from the arm, when it becomes necessary to remove blood, for the purpose of relieving inflammation of the eye: it is convenient for the patient and the surgeon; it is an operation easily performed; it occasions very little pain; the hæmorrhage can be readily controlled, without a necessity for uncomfortable bandaging; and you may obtain from a proper orifice any quantity of blood you may deem it requisite to abstract. Dr. Vetch, who strongly advises one large bleeding to the production of syncope, in all cases of acute inflammation of the eye, says, "the salutary effect of syncope I can only ascribe to the laxity of the vessels, rendering them unable to resume their former tone and state of excitement; and it is only as far as we hold this specific effect in contemplation, that venesection is to be regarded as a principal remedy in the treatment of ophthalmia. The strength and fibre of the patient may be reduced by abstinence and bloodletting to the lowest standard, without producing any material benefit, or insuring the organ against the destructive consequence of the further progress of inflammation." Although I do not conceive the opinions contained in the preceding paragraph to be absolutely correct, I have thought it right to present you with the opinions of a gentleman who had considerable experience in diseases of the eye, on this important part of the treatment of ophthalmic affections.

Having made an impression on the system by general bleeding, you may perhaps consider it necessary to apply leeches, for the removal of what may be termed a secondary degree of inflammation (subacute): a dozen leeches may be placed just beneath the tarsal border of the lower eyelid, and in this way you may obtain a considerable quantity of blood. There are, however, certain objections to the use of leeches in this situation, which it is proper to mention:—they occasion an exposition of the inflamed eye to light, unless applied with more care than is customarily employed by those whose proper business it is to apply them; they also give rise to an unpleasant degree of swelling and ecchymosis of the lids, particularly if the patient pos-

sesses an irritable skin, or unusually great susceptibility of constitution; and they sometimes cause, in children particularly, a troublesome hæmorrhage, which seriously alarms the patient and his friends.

There are surgeons who profess to produce great advantage from scarifying the inflamed conjunctiva, (I am not now speaking of chemosis): they divide the numerous large vessels you may discover on everting the lids, by repeated incisions with a lancet; and of course you may in this way induce a pretty copious discharge of blood; but, as might be imagined, these incisions, by destroying the smoothness of the mucous surface, as also by the direct and immediate injury they inflict, give rise to great pain and uneasiness, and, in the majority of instances, produce an extent of secondary inconvenience more than equivalent to the immediate relief to be obtained from them. It is not certainly a very consistent mode of diminishing inflammation of a part so delicately formed and peculiarly circumstanced as the interior of the eyelids, in reference to the freedom and frequency of their movements upon the eyeball. This practice is, however, sanctioned by many excellent surgeons, and among others by Professor Beer and the late Mr. Ware.

It was formerly rather a favourite practice to rub the everted surface of the eyelids with "barley boards," with a view of lessening their vascularity, by abstracting a large quantity of blood from the part immediately inflamed: you will not be surprised to learn that this barbarous mode of scarifying the conjunctiva has been discontinued.

It must be understood that no directions you can receive from books or lectures will enable you to decide upon the quantity of blood it may be necessary to withdraw, in every case of acute inflammation of the textures of the eye; there must be a demand, a very great demand, on your own judgment: I cannot tell you that the loss of so many ounces of blood will be necessary to subdue a certain degree of inflammation of the conjunctiva, and that the abstraction of so many more or less number of ounces will be required to remove inflammation of the sclerotica, and so on, with regard to the inflammation of the other textures of the eye. However, the following directions comprehend the rules which regulate my own practice:—you must be guided by the effects of bleeding upon the constitution, as well as by its influence upon the eye; you must bleed repeatedly in a very short space of time, if symptoms are severe; for, as I may again remark, unless you abridge the duration of acute inflammation—unless you check its progress with promptitude, interstitial deposition may take place, and you may experience the disappointment, and your patient may sustain the injury, of recovering the form of the eye perhaps, but with loss of the transparency of its pellucid textures, after having cheerfully submitted to that treatment, which, if carried a slight degree farther, would have perfectly preserved both its figure and its transparency.

You will find it necessary, in order to complete the intentions comprised in this division of the treatment, to administer, at the commencement of the attack, an ample dose of calomel and jalap, and to maintain free secretions from the intestines by the aid of saline purgatives; and you may also have occasion to prescribe, in robust habits especially, nauseating doses of tartarized antimony, to produce that depression of the circulating system, favourable in the subsidence of inflammatory action, and also such other remedies as you may consider best calculated to promote the exhaling function of the skin; and of course it will be absolutely indispensable to lower the diet, and restrict your patient to a mild, and almost fluid, sustenance.

You were told that an exclusion of light from the eye, and an immunity from its ordinary action, were necessary aids to our treatment. It is an admitted principle, that in the treatment of an acute inflammatory affection of any organ, its function should, as far as possible, be dispensed with; and I need not tell you in what manner this object is best accomplished, as respects the organ of vision. Now as the retina is always more or less affected in every acute inflammation of the textures of the eye, you would of course deem it necessary to protect the eye, when inflamed, from the stimulus of light—more or less completely, as the inflammation may be acute or otherwise, or as the part affected may be more or less near in its situation, or related in its function, to the retina; and as the movements of the eyelids occasion pain, and the actions of the muscles of the globe, by moving or compressing it, give rise to great uneasiness, these motions should be prevented; and this is generally sufficiently accomplished by the suspension of a fold of linen before the affected part. Of course attention to these measures becomes important in proportion as the inflammation is severe, and the texture in which it is situated deep-seated: the remedies employed for the cure of iritis, retinitis, and choroiditis, are much assisted by the absolute exclusion of light, while it is only necessary to protect the eye from its more brilliant rays, when the inflammation is situated in the conjunctiva and the sclerotica.

It is perhaps needless to say any thing respecting the necessity of rectifying any disorder of the alimentary canal which may be discovered in a case of this

kind: you will remember how highly important it is not to overlook so necessary a means of aiding the efficacy of your other remedies: do not let a neglect on this point lead to the failure of an otherwise judiciously regulated plan of treatment; and allow me to say, that whilst you are omitting to attend to the state of the stomach and bowels, where such attention is required, you are allowing that condition of things to remain which has most probably caused, and will maintain and aggravate, the malady you are so solicitous to relieve and remove.

Counter-irritation.

We now proceed to the consideration of Counter-Irritation, and as my experience in the management of affections of the eye has caused me to place great reliance on its utility, I shall solicit your attention for a short time to my remarks on this very useful and interesting part of the treatment of ophthalmic diseases. We shall first speak of the best mode of employing counter-irritation; secondly, endeavour to demonstrate the most judicious time for its employment; and, lastly, point out its most appropriate situation.

The most usual modes of effecting counter-irritation are, by irritating the skin by various stimulating liniments and unguents; by impairing or destroying its vitality by the aid of moxa, and various caustic substances; or, by inserting some foreign substance into a wound made with a surgical instrument, as is exemplified in the seton and issue.

The advantages connected with the use of blisters are—the speed with which they produce their effect, their convenience of application, and the quick subsidence of their effects, when no longer required to remain, on the application of any mild ointment. If, however, the patient possess an irritable skin, or be subject to attacks of erysipelatous inflammation—if it be desirable to maintain counter-irritation for a long time, or if former experience has proved that blisters are likely to affect the urinary organs—you would, in such cases, adopt some other mode of effecting your object.

There are many surgeons who are extremely partial to the mode of irritating the skin by frictions with liniments and ointments, but the effects of such applications are exceedingly uncertain; in many cases they will produce no effect whatever, while in other instances they will excite the most intense inflammation, and even superficial sloughing; besides, they are generally a long time before they produce their effect: your patient may rub for many days before he produces any useful effect upon the skin.

In the course of my practice I have very frequently effected great benefit in the cases under consideration, by the aid of setons and issues, and as they are easily made, and formed without occasioning much pain—as they are conveniently dressed, and are perfectly manageable as to the increase or diminution of their size, and as they combine a moderate degree of counter-irritation, with a salutary amount of discharge—I have not seen advantages in the more recent discoveries to alter my opinion of their utility, or to induce me to prefer them, for the cure of this class of diseases, to remedies whose value has been decidedly ascertained.

You will imagine that a remedy for a disease, like advice needlessly given, or too perseveringly obtruded, may be out of season, and in fact there are few remedies so greatly mismanaged, as regards the time of their application, as counter-irritants; persons will often come to you with their eyes most acutely inflamed, with a blister upon the forehead or temple, or even upon the eye-lids, and they will tell you, with a foolish face of astonishment and chagrin, that the blister you ordered them on a former occasion, when their eyes were inflamed, cured them, but that now it has increased their sufferings. Undoubtedly much depends on selecting the appropriate period for their employment, and it will be remembered that in acute inflammation of the eye they are never to be used as a first application, and are never to be placed very near to the affected organ until the inflammation has been considerably reduced. You may prescribe blisters (presuming the inflammation of the eye to be of an acute character) after ample venesection has been premised, and you may repeat them, if the acute symptoms are merely diminished; or if it be desirable, either from the lingering nature of the disease, or an obvious tendency to a relapse, you may form an issue in the arm or temple, or insert a seton at the back of the neck. But on this subject I shall speak more fully when considering strumous disease of the eyes.

With regard to the situation in which it may be most desirable to employ counter-irritants, you are aware that it is usual to employ a blister at the back of the neck, or behind each of the ears, after bleeding has been premised, and that it is desirable afterwards to place them nearer to the seat of the disease. You may, in fact, put one over the eye-brow, on one or both sides, as you may have one or both organs affected, or if you prefer it, upon the temples; or, if the secondary set of symptoms evince a disposition to be lingering in their duration, a more permanent form of counter-irritation, such as an issue in the arm, may be necessary. This is indeed a most convenient

situation for the purpose; the issue does not, or scarcely at all, disfigure the arm, and is so conveniently managed by patients that they rarely complain of the trouble of dressing it; and it may be added, so great and so evident are the benefits conferred by a small issue of this description, not only upon the eye but also upon the general health, that they will be frequently as reluctant to have them healed as they had formerly been averse to permit their formation. As it will be necessary for me to advert to this subject occasionally, whenever it may be requisite to mention the adaptation of remedies to particular forms of disease, I shall not extend my observations by pointing out in detail the description of case suited to each particular remedy of this class, but content myself with thus directing your attention to the subject in this general manner, in the hope of impressing upon your minds the high value of this class of remedies.

Collyria.

We proceed, lastly, to speak of those local applications which are intended to abstract heat from the inflamed part, or allay irritation and soothe pain; and here let me not be understood to advise any one of the collyria, and other applications to be presently recommended, to be persevered in to the exclusion of any other from which the patient experiences a greater amount of relief: you know the intention they are designed to fulfil, and you know also that if they are painful on their first application, and are not succeeded by relief, they cannot be serviceable, and therefore ought not to be continued. You are too well aware of the varied susceptibilities and peculiarities of different individuals to expect that any one application will be universal in its adaptation. You will generally find the common goulard water, used warm or cold, as may be most comforting to the patient's feelings, serviceable on the first accession of inflammation, and afterwards, as the symptoms decline, a weak solution of the sulphate of zinc may be advantageously substituted; or, if the pain be severe, it may be necessary to foment the eyes frequently with warm water, a strong decoction of poppies, or an aqueous solution of opium; but I again repeat, that should any of these applications appear to be injurious, they must be changed for some other, or used in a different manner; for instance, you may find on inquiry that the goulard water has been applied when quite cold, and has aggravated the sensation of heat and pain in the eye it was meant to relieve, and if you direct it to be warmed and then used, it will, in many instances, answer the intended purpose most completely.

There are various agents by the assistance of which these applications are allowed to operate upon the eye, and it is astonishing with what pertinacity some practitioners will cling to their own favourite plan, to the utter exclusion of every other: some will prefer bathing the eye with a sponge, or a fold of soft linen, and others use what is termed the eye-glass—a vessel adapted to the shape of the orbit, which when filled with the collyrium is inverted, and placed upon the eye, so that its contents are permitted to dwell upon the surface of that organ. Any of these modes will answer the purpose very well, provided that no active friction be employed. We will not contend for straws.

ON HYBERNATION.

By Marshall Hall, M.D.
F.R.S.E. M.R.I. &c. &c.

[Concluded from page 211.]

2. *Of the Irritability.*

The single fact of a power of sustaining the privation of air, without loss of life, leads alone to the inference that the irritability is greatly augmented in the state of hybernation. This inference flows from the law so fully stated in my former paper, and the fact is one of its most remarkable illustrations and confirmations.

It might have been inferred from these premises, that the beat of the heart would continue longer after decapitation in the state of hybernation, than in the state of activity in the same animal; an inference at once most singular and correct.

This view receives the fullest confirmation from the following remarkable experiment: On March the 9th, soon after midnight, I took a hedgehog which had been in a state of uninterrupted lethargy during 150 hours, and divided the spinal marrow just below the occiput; I then removed the brain and destroyed the whole spinal marrow as gently as possible. The action of the heart continued vigorous during four hours, when, seeing no prospect of a termination to the experiment, I resolved to envelop the animal in a wet cloth, and leave it until early in the morning. At 7 o'clock A.M. the beat of both sides of the heart still continued. They still continued to

move at 10 A.M., each auricle and each ventricle contracting quite distinctly. At half-after 11 A.M. all were equally motionless; yet all equally contracted on being stimulated by the point of a penknife. At noon the two ventricles were alike unmoved on being irritated as before; but both auricles contracted. Both auricles and ventricles were shortly afterwards inirritable.

This experiment is the most extraordinary of those which have been performed upon the mammalia. It proves several interesting and important points: 1. That the irritability of the heart is augmented in continued lethargy in an extraordinary degree. 2. That the irritability of the left side of the heart is then little, if at all, less irritable than the right,—that it is, in fact, veno-contractile. 3. That, in this condition of the animal system, the action of the heart continues for a considerable period independently of the brain and spinal marrow.

On April the 20th, at six o'clock in the evening, the temperature of the atmosphere being 53°, a comparative experiment was made upon a hedgehog in its state of activity: the spinal marrow was simply divided at the occiput; the beat of the right ventricle continued upwards of two hours, that of the left ventricle ceased almost immediately; the left auricle ceased to beat in less than a quarter of an hour; the right auricle also ceased to beat long before the right ventricle.

3. *Of the Sensibility.*

All the writers upon the subject of hybernation agree in stating that the sensibility is greatly impaired; and it is impossible to commit a greater mistake.

The slightest touch applied to one of the spines of the hedgehog immediately rouses it to draw that deep inspiration of which I have spoken. The merest shake induces a few respirations in the bat. The least disturbance, in fact, is felt, as is obvious from its effect in inducing motion in the animal.

It is from the misconception on this point that the error has arisen, that the respiration is not absolutely suspended in hybernation. This function has been so readily excited, through the medium of an unimpaired sensibility, that the event has been considered as appertaining to the state of hybernation.

In fact, the sensibility is in nearly the same condition in hybernation as in ordinary sleep.

It must appear extraordinary, that with an unimpaired sensibility there can co-exist a suspended respiration. Why is not this suspension of respiration painful in the hybernating, as in other animals? And why is not the animal roused, by this pain, from its slumbers, if its sensibility be only slightly impaired?

But we should first ask, what are the precise seat and source of that pain which is felt during the suspension of respiration? These are, I think, demonstrably, the heart, and an impeded circulation through this organ. If, therefore, the circulation through the heart be not obstructed, there will be no painful sensation. Now is it precisely the peculiar property of hybernation, that the circulation through the heart is *not* interrupted, although the respiration be suspended. This topic is reserved, however, for a subsequent part of this paper. It is simply stated in this place as a fact, to shew that the painful feelings supposed to arise from suspended respiration in hybernation, do not exist; and that the difficulty of supposing a suspended state of the respiration with an unimpaired sensibility, is, in this manner, entirely removed.

The sensorial functions, on the other hand, are nearly suspended. This is proved by the suspension of respiration, which is immediately renewed for a time, on exciting the animal. It is further proved by the fact, that although the animal coils itself up when touched, it immediately relaxes into the former position; whereas, when it is awake, the impression of an external object induces a state of contraction and immobility which is continued for some time,—probably as long as the sense of fear continues. When the hedgehog, coiled up in its state of activity, is thrown into water, it immediately relaxes itself, from fear, and betakes itself to swimming; in the state of lethargy, on the other hand, no fear appears to be excited under such circumstances, and the animal would probably remain still and quiet for a very considerable period, if its sensibility were not acted upon by the contact of the water.

4. *Of the Muscular Motility.*

The motility of the muscles, in true

hybernation, is, like the sensibility, unimpaired. Those physiologists who have asserted the contrary, have, as will be shewn shortly, mistaken the phenomena of torpor from cold, for those of true hybernation.

If the hedgehog, in a state of the most perfect lethargy, uncomplicated with torpor, be touched, its respiration is resumed, and it coils itself up more forcibly than before. The dormouse, in similar circumstances, unfolds itself; and the bat moves variously. Not the slightest stiffness is observed. The hedgehog, when roused, walks about, and does not stagger, as has been asserted. The bat speedily takes to the wing, and flies about with great activity, although exhaustion and death may subsequently result from the experiment. The phenomena are similar to those of awaking from natural sleep. Insensibility, impaired motility, stiffness, lameness, &c. belong to torpor, and not to true hybernation.

5. *Of the Circulation.*

The wing of the bat affords an admirable opportunity of observing the condition of the circulation during hybernation. But it requires peculiar management. If the animal be taken from its cage, and the wing extended under the microscope, it is roused by the operation, and its respiratory and other movements are so excited, that all accurate observation of the condition of the circulation in the minute vessels is completely frustrated. Still greater caution is required in this case, than even in the observation of the respiration and temperature.

After some fruitless trials, I at length succeeded perfectly in obtaining a view of the minute circulation undisturbed. Having placed the animal in its state of hybernation, in a little box of mahogany, I gently drew out its wing through a crevice made in the side of the box; I fixed the tip of the extended wing between portions of cork; I then attached the box and the cork to a piece of plate-glass; and, lastly, I left the animal in this situation, in a cold atmosphere, to resume its lethargy.

I could now quietly convey the animal ready prepared, and place it in the field of the microscope without disturbing its slumbers, and observe the condition of the circulation.

In this manner I have ascertained, that, although the respiration be suspended, the circulation continues uninterruptedly. It is slow in the minute arteries and veins; the beat of the heart is regular, and generally about twenty-eight times in the minute.

We might be disposed to view the condition of the circulation in the state of hybernation as being reptile, or analogous to that of the batrachian tribes. But when we reflect that the respiration is nearly, if not totally, suspended, and that the blood is venous, we must view the condition of the circulation as in a lower condition still, and, as it were, sub-reptile. It may, indeed, be rather compared to that state of the circulation which is observed in the frog from which the brain and spinal marrow have been removed by minute portions at distant intervals.

In fact, in the midst of a suspended respiration, and an improved condition of some other functions, one vital property is augmented. This is the irritability, and especially the irritability of the left side of the heart. The left side of the heart, which is, in the hybernating animal, in its state of activity, as in all the other mammalia, only arterio-contractile, becomes veno-contractile.

This phenomenon is one of the most remarkable presented to me in the whole animal kingdom. It forms the single exception to the most general rule, amongst animals which possess a double heart. It accounts for the possibility of immersion in water or a noxious gas, without drowning or asphyxia; and it accounts for the possibility of a suspended respiration, without the feeling of oppression or pain, although sensation be unimpaired. It is, in a word, this peculiar phenomenon, which, conjoined with the peculiar effect of sleep in inducing diminished respiration in hybernating animals, constitutes the susceptibility and capability of taking on the hybernating state. On the other hand, as the rapid circulation of a highly arterialized blood in the brain and spinal marrow of birds probably conduces to their activity, the slow circulation of a venous blood doubtless contributes to the lethargy of the hybernating animal.

6. *Of the Digestion.*

There is much difference in the powers of digestion, and in the fact of omitting to take food, in the hybernation of different animals. The bat, being insectivorous, would awake in vain; no

food could be found: the hedgehog might obtain snails or worms, if the ground were not very hard from frost: the dormouse would find less difficulty in meeting with grain and fruits. We accordingly observe a remarkable difference in the habits of awaking from their lethargy or hybernation, in these different animals.

I have observed no disposition to awake at all in the bat, except from external warmth or excitement. If the temperature be about 40° or 45°, the hedgehog, on the other hand, awakes, after various intervals of two, three, or four days passed in lethargy, to take food; and again returns to its state of hybernation. The dormouse, under similar circumstances, awakes daily.

Proportionate to the disposition to awake and take food, is the state of the functions of the stomach, bowels, and kidneys. The dormouse and the hedgehog pass the fæces and urine in abundance during their intervals of activity. The bat is scarcely observed to have any excretions during its continued lethargy.

In the dormouse and the hedgehog, the sense of hunger appears to arouse the animal from its hybernation, whilst the food taken conduces to a return of the state of lethargy. It has already been observed, that there are alternations between activity and lethargy in this animal, with the taking of food, in temperatures about 40° or 45°. Nevertheless, abstinence doubtless conduces to hybernation, by rendering the system more susceptible of the influence of cold, in inducing sleep and the loss of temperature. The hedgehog, which awakes from its hybernation, and does not eat, returns to its lethargy sooner than the one which is allowed food.

III. Of Torpor from Cold.

It is highly important, and essential to the present investigation, to distinguish that kind of torpor which may be produced by cold in any animal, from true hybernation, which is a property peculiar to a few species. The former is attended by a benumbed state of the sentient nerves, and a stiffened condition of the muscles; it is the direct and immediate effect of cold, and even in the hybernating animal is of an injurious and fatal tendency; in the latter, the sensibility and motility are unimpaired, the phenomena are produced through the medium of sleep; and the effect and object are the preservation of life.

Striking as these differences are, it is certain that the distinction has not always been made by former observers. In all the experiments which have been made, with artificial temperatures especially, it is obvious that this distinction has been neglected.

True hybernation is induced by temperatures only moderately low. All hybernating animals avoid exposure to extreme cold. They seek some secure retreat, make themselves nests or burrows, or congregate in clusters, and, if the season prove unusually severe, or if their retreat be not well chosen, and they be exposed in consequence to excessive cold, many become benumbed, stiffen, and die.

In our experiments upon hybernation we should imitate nature's operations.

To induce true hybernation, it is quite necessary to avoid extreme cold; otherwise we produce the benumbed and stiffened condition to which the term torpor or torpidity may be appropriated. I have even observed that methods which secure moderation in temperature, lead to hybernation: hedgehogs supplied with hay or straw, and dormice, supplied with cotton wool, make themselves nests, and become lethargic; when others, to which these materials are denied, and which are consequently more exposed to the cold, remain in a state of activity. In these cases, warmth or moderated cold, actually concur to produce hybernation.

When we read of insensibility, of a stiffened state of the muscles, and of a cessation of the circulation, as obtaining in hybernation, we may be certain that a state of torpor has been mistaken for that condition. The actually hybernating animal exposed to continued severe cold, is, as M. Saissy correctly observes, first roused from this state of ease and preservation, into a painful activity, and then plunged into a fatal torpor.

IV. Of Reviviscence.

Not the least interesting of the phenomena connected with hybernation, are those of reviviscence. Hybernation induces a state of irritability of the left side of the heart, which, with high respiration and an arterialized blood, would be incompatible with life. Respiration

suddenly restored, and permanently excited, is therefore as destructive as its privation in other circumstances.

All those bats which were sent to me from distant parts of the country died. The continued excitement from the motion of the coach, keeping them in a state of respiration, the animal perished. One bat had, on its arrival, been roused so as to fly about. Being left quiet, it relapsed into a state of hybernation. The excitement being again repeated the next day, it again flew about the room: on the succeeding day it was found dead.

It is in accordance with this law that we observe hybernating animals adopting various measures to secure themselves from frequent sources of disturbance and excitement. They choose sheltered situations, as caverns, burrows, &c., secure from the rapid changes and the inclemencies of the weather and season. Many form themselves nests; others congregate together. The hedgehog and the dormouse roll themselves up into a ball. The common bat suspends itself by the claws of its hinder feet, with its head dependent, generally in clusters; the horse-shoe bat, (ferrum equinum,) spreads its wings so as to embrace and protect its fellows.

All these circumstances are obviously designed to prevent disturbed hybernation.

In the depth of caverns, and other situations sheltered from changes of temperature in the atmosphere, the calls of hunger are probably the principal cause of revivisecence in the spring. The other causes of revivisecence are the return of warmth and external excitements: it is interesting to observe and trace the gradual return of respiration in the former case, and of the temperature of the animal in the latter.

If the hybernating hedgehog be touched even very gently, it draws a deep breath, and then continues to breathe for a short time. If this excitement be repeated, the animal is permanently roused, and its temperature raised. If the temperature of the atmosphere be augmented, the respiration is gradually excited, and the animal is gradually restored to its state of activity.

If a hybernating animal be excited in a very cold atmosphere, its temperature rises variously, and then falls. A bat was perfectly lethargic in a temperature of 36°. A fine thermometer, with a cylindrical bulb, was introduced into its stomach; it rose to 39°. One hour afterwards, the animal not being further disturbed, the respiration was rapid, and the temperature in the stomach 95°. Shortly afterwards the temperature was 90°. The minute circulation was pretty good, and pulsatory in the arteries, the heart beating from twenty-eight to thirty-six times in the minute.

In another bat, in an atmosphere of the temperature of 36°, the thermometer in the stomach rose to 39°. The animal being continually excited, the temperature rose to 65°, but speedily fell to 60.

The animal excited and revived in this manner, is in a state of exhaustion and inanition. It is incapable of maintaining its temperature, if exposed to cold, and will die unless it repass into the state of hybernation. It may be compared to the state of the mouse deprived of food in the following experiment of Mr. Hunter. "A mouse was put into a cold atmosphere of 13° for an hour, and then the thermometer was introduced as before; but the animal had lost heat, for the quicksilver at the diaphragm was carried only to 83°, in the pelvis to 78°."

"In order to determine whether an animal that is awakened has the same powers, with respect to preserving heat and cold, as one that is vigorous and strong, I weakened a mouse by fasting, and then introduced the bulb of the thermometer into its belly; the bulb being at the diaphragm, the quicksilver rose to 97°; in the pelvis to 95°, being two degrees colder than the strong mouse: the mouse being put into an atmosphere as cold as the other, and the thermometer again introduced, the quicksilver stood at 79° at the diaphragm, and at 74° in the pelvis.

"In this experiment, the heat at the diaphragm was diminished 18°, in the pelvis 21°.

"This greater diminution of heat in the second than in the first, we may suppose proportional to the decreased power of the animal, arising from want of food*."

But extreme cold alone, by a painful effect induced on the sentient nerves, rouses the hybernating animal from its lethargy, as has been remarked already, and is illustrated by the following experiments of Hunter. "Having brought a

* Animal Economy, pp. 114, 115.

healthy dormouse, which had been asleep from the coldness of the atmosphere, into a room in which there was a fire, (the atmosphere at 64°,) I introduced the thermometer into its belly, nearly at the middle, between the thorax and pubis, and the quicksilver rose to 74° or 75°; turning the bulb towards the diaphragm, it rose to 80°; and when I applied it to the liver, it rose to 81½.

" The mouse being placed in an atmosphere at 20°, and left there half an hour, when taken out was very lively, even much more so than when put in. Introducing the thermometer into the lower part of the belly, the quicksilver rose to 91°; and upon turning it up to the liver, to 93°.

" The animal being replaced in the cold atmosphere at 30°, for an hour, the thermometer was again introduced into the belly: at the liver it rose to 93°; in the pelvis to 92°; the mouse continuing very lively.

" It was again put back into an atmosphere cooled to 19°, and left there an hour: the thermometer at the diaphragm was 87°; in the pelvis 83°; but the animal was now less lively.

" Having been put into its cage, the thermometer being placed at the diaphragm, in two hours afterwards, was at 93° *".

In these experiments the animals appear to have been roused partly by the state of the wound in the abdomen, but chiefly by the extreme cold. They can scarcely, however, be considered as experiments upon hybernation, however interesting they may be in reference to reviviscence from that state.

The fact of the fatal influence of excited respiration during the augmented irritability of hybernation, contrasted with the similar effect of suspended respiration, during the diminished irritability of the state of activity, will illustrate many of the causes, kinds, and phenomena of death. Do not these resolve themselves, in fact, into irritability insufficiently or excessively excited?

Recapitulation.

The object of this paper has been to treat of the singular phenomena of hybernation, and especially to point out the remarkable application of the law stated in my former paper, to the active and lethargic states of the hybernating animal.

1. The natural sleep of the hybernating animal differs greatly, yet only in degree, from the sleep of any other animal.

2. This sleep passes insensibly into the state of true hybernation, which is more profound, as the blood loses its arterial character; for,

3. In hybernation, the respiration and the evolution of heat are nearly suspended.

4. The irritability is, at the same time, singularly augmented; and the animal bears proportionately the privation of air.

5. The nervous sensibility and the muscular motility are unimpaired.

6. There is the singular phenomenon of this unimpaired sensibility, and the capability of bearing the privation of air without pain; a fact which receives an interesting and perfect explanation from the additional fact of the augmented irritability or veno-contractility of the left side of the heart.

7. There is an important distinction between true hybernation and torpor from cold, not attended to by physiologists.

8. Severe cold, like all other causes of pain, rouses the hybernating animal from its lethargy; and, if continued, induces the state of torpor.

In conclusion, one of the most general effects of sleep, is to impair the respiration, and with that function, the evolution of animal temperature. The impaired state of the respiration, induces a less arterial condition of the blood, which then becomes unfit for stimulating the heart; accumulation of the blood takes place in the pulmonary veins and left auricle: a sense of oppression is induced, and the animal is either roused to draw a deep sigh, or awakes altogether.

Such are the phenomena in animals in which the heart has not the faculty of taking on an augmented state of irritability, with this lessened degree of stimulus. But in those animals which do possess this faculty, a property which constitutes the power of hybernation, the heart continues the circulation of the blood more slowly indeed, but not less perfectly, although its arterial character be diminished and its stimulant property impaired. No repletion of the pulmonary veins and of the left auricle, no sense of oppression is induced, and the animal is not roused; the respiration

* Animal Œconomy, pp. 111, 112.

continues low, the temperature falls, and the animal can bear, for a short period, the abstraction of atmospheric air.

All the phenomena of hybernation originate, then, in the susceptibility of augmented irritability. The state of sleep, which may be viewed as the first stage of hybernation, induces an impaired degree of respiration. This would soon be attended with pain, if the irritability of the heart were not at the same time augmented, so as to carry on the circulation of a less arterial blood, and the animal would draw a deep sigh—would augment its respiration, or awake. Occasional sighs are, indeed, observed in the sleep of all animals, except the hybernating. In these, the circulation goes on uninterruptedly, with a diminished respiration, by the means of an augmented irritability. There is no stagnation of the blood at the heart, consequently no uneasiness; and the animal becomes more and more lethargic, as the circulation of a venous blood is more complete. This lethargy is eventually interrupted by circumstances which break ordinary sleep, as external stimuli, or the calls of appetite.

Moderate cold disposes to sleep,—to lethargy. But severer cold induces a different condition of the system,—that of torpor. Sleep is the *medium* between such moderate cold and the phenomena of hybernation; torpor is the *immediate* effect of the severer degrees of cold.

This investigation naturally leads to that of the comparative conditions of the respiration and of the irritability, in the pupa and perfect states of some species of the insect tribes. There is much reason to suppose that these states are respectively similar to those of lethargy and activity in the hybernating animal.

CASE OF SUBCLAVIAN ANEURISM.

By W. P. Nichols, Esq.
Lecturer on Anatomy, and Senior Surgeon to the Guardian's Dispensary, Norwich.

To the Editor of the Medical Gazette.

Sir,

Early in April last I was consulted by Miss Newman, a young lady, æt. 21, who resided in the vicinity of Norwich, respecting a pulsating tumor in her neck, which made its appearance immediately after she had subjected her left arm to severe and unusual exertion in saving herself from a fall.

On examination, I found a tumor, the size of a hen's egg, situated in the left side, occupying the triangular space which is bounded below by the clavicle; on the inner side, by the clavicular portion of the mastoid muscle; and on the outer side, by the anterior fibres of the trapezius: evidently the result of some injury done to the subclavian artery in that part of the canal which stretches from the edge of the scalenus muscle towards the axilla, before it has passed under the clavicle. Indeed, so near the edge of the scalenus was the injury, that I was not able to compress the vessel with my thumb between that muscle and the tumor.

The aneurismal nature of the swelling being very evident, I did not think it desirable at that time to apprize the patient of the formidable character of the tumor; but, directing her to remain quiet, I gave her some aperient medicine, promising to see her again in a few days; when I explained to her fully her situation, and the mode of treatment which I proposed to adopt. She assented, and the operation of securing the vessel above the aneurism was performed in the following manner.

April 30th, 11 A.M.—The patient was placed, in an horizontal position, on a table about three feet in height, having her head hanging over the end, and supported by an assistant. The integuments being drawn down, an incision was then made through the skin and platysma myoides, along the clavicle, three inches in length, from the outer fibres of the clavicular portion of the sterno-cleido-mastoideus outwards: another incision was carried from the inner point of the former one upwards, along the clavicular portion of the sterno-cleido-mastoideus, for four inches; this incision passed between the fasciculi of the platysma myoides, which in this case were remarkably large. The triangular flap formed by the two incisions, was dissected back, carrying with it, imbedded in its substance, the external jugular vein, as far as the tumor would allow of its being done; and a little dissection now brought into view the omo-hyoideus at the upper part, passing obliquely upwards to its insertion. This muscle was divided, and a small artery passing across the wound, immediately

below it, was secured. The deep fascia of the neck was here exposed, having on the inner side the middle scalenus beautifully distinct, and passing to its insertion into the tubercle of the rib. By slightly rotating the head, the different direction of its fibres from those of the sterno-cleido-mastoideus became remarkably apparent; shewing how important, at this stage of the operation, it is that this muscle should be your guide. The fascia was then cautiously divided along the outer edge of the scalenus, and the transverse artery of the neck drawn upwards by a blunt hook, whilst the large vein which accompanies it, but which crosses the wound considerably lower down, was secured by two silk ligatures, and divided. This enabled me to pass my finger along the scalenus to the tubercle of the rib, and to compress the artery where it leaves the chest about half an inch above that process. The space, however, between the aneurismal tumor and the scalenus was so small that it was thought advisable to divide a few of its fibres, in order the more readily and securely to tie the vessel. This having been done, a strong blunt aneurismal needle, armed with a silk ligature, was very readily passed under the artery from below, and its blunt extremity having been pressed upwards, I cut through the cellular tissue upon it, and thus passed the instrument without detaching the vessel from its connexions. The ligature was tied with great ease, and the tumor immediately subsided. All pulsation ceased from that time; the edges of the wound were brought together by means of a suture and some adhesive plaister, and the patient returned to her bed. She bore the operation with remarkable firmness throughout.

April 30th, 4 P.M.—Pulse 70; skin hot and dry, and very restless.

Træ. Opii, gtt. xxx.

9 P.M.—In profuse perspiration; pulse 96; slept soundly at intervals.

May 1st, 8 A.M.—Pain abated; slept soundly for several hours.

9 P.M.—Pulse 90; mind tranquil.

Træ. Opii, gtt. xxx.

2d, 8 A.M.—Pulse 96; generally better.

10 P.M.—Pulse the same; altogether easier.

Pil. Aperient. ij.

3d, 9 A.M.—Pulse 80; complains of want of sleep, and feverish; the bowels have not been relieved.

10 P.M.—Bowels relieved.

4th, 9 A.M.—Pulse during night 100, but towards morning 90. Wound dressed; to all appearance likely to heal by first intention; much lymph thrown out, and general appearance of the wound healthy. Skin moist; healthy tongue, and every symptom denoting improvement. Bowels relieved copiously.

Omit. Tra. Opii.

5th, 10 A.M.—Pulse 96; rested well; tongue clean; skin moist; bowels rather relaxed.

Træ. Catechu, gtt. xv. Vespere.

6th, 10 A.M.—Pulse 84; continues improving in every respect; bowels regular.

7th, 11 A.M.—Pulse 80; skin cool; wound dressed, looking healthy; bowels quiet; doing well.

8th, 9 A.M.—In every respect the same.

9th, 11 A.M.—Wound dressed, upper portion healing by first intention; pulse 86.

10th, 9 A.M.—Wound looking well; discharge copious.

11th, 10 A.M.—Bowels regular; pulse 80. Two of the ligatures came away today.

13th, 10 A.M.—The pulse in the radial artery returned.

15th, 9 A.M.—Complains of slight pain and numbness in the wound; pulse 75; bowels regular.

16th, 10 A.M.—Pain gone; improving.

20th.—Ligature came away.

23d.—Cured.

November.—Up to the present time the patient has enjoyed perfectly good health, and feels no inconvenience resulting from the operation.

I have transmitted the preceding case of subclavian aneurism for insertion in your valuable journal, not because I consider that the propriety of performing the operation has not been set at rest by the successful result of former cases, but because, at the present moment, their number is so small that additional ones are desirable, to shew that it is not so fearful an operation as the instances of success, compared with those of fatal termination, might at first induce us to suppose.

There are also, in the favourable cases

which have been recorded, very few, if any, in which some unpleasant occurrences have not taken place during their progress towards a cure, and which additional experience will not in some degree obviate.

In this case, the circumstances which I consider of importance are these:

The position of the patient, who was placed horizontally, with the head (as described) hanging over the end of the table; which position contributed very materially to facilitate the different steps of the operation. The space is thus completely exposed, the light falls fully on the part where it is of the most importance, and the operator is not confused by the presence of any accumulation of blood at the bottom of the wound.

The turning back of the jugular vein imbedded in the flap; thus placing it beyond the chance of injury at the time of, or subsequently to, the operation.

The practicability of performing this operation without detaching the sterno-cleido-mastoid muscle from its clavicular origin, although the tumor was situated above the clavicle.

The drawing upwards of the transverse artery, and thus leaving it undivided; by which this vessel (becoming enlarged as the circulation in the extremity grows more free) becomes one of the principal trunks in subsequently supplying blood to the limb.

That no unfavourable symptoms were produced by the division of, and tying, the accompanying vein (which, in this instance, could not be avoided).

Lastly, the passing the aneurismal needle under the vessel, without separating it from its connexions, which may be readily effected; and of tying it beneath the outer fibres of the scalenus: which fact appears to me valuable, inasmuch as it proves that the very short distance between the ligature and the thyroid axis affords sufficient space for the formation of a coagulum, and the consequent obliteration of the arterial tube.

I received much and valuable assistance from Dr. Wright, Dr. Lubbock, and Mr. Norgate; to whom I beg leave thus publicly to express my thanks.

I am, sir,
Your obedient servant,
W. P. Nichols.

PERFORATION OF THE STOMACH FROM ULCERATION.

To the Editor of the Medical Gazette.

Sir,

If you think with me that the following case is worthy of publication, it is at your service.

I have the honour to be, sir,
Your obedient servant,
James Hurd.

Cleeve Cottage,
Yatton, near Bristol, Nov. 6, 1832.

Feb. 25, 1832.—In the afternoon I was called to attend Robert Venn, gardener, æt. 60, a temperate and industrious man, who had for many years suffered from ulcerated legs, which were still discharging: he had also for a great number of years complained of occasionally dyspeptic symptoms, which had latterly been more constant and severe, yet he had not at any time ceased to follow his avocation. The bowels were habitually disposed to constipation. From the 22d instant he had experienced frequent rigors, and had lost all desire for food: on the evening of the 23d he took two laxative pills, which moved the bowels once on the following morning, since which time they had not been evacuated. On rising to-day, the 25th, he complained of being more indisposed, but had no particular symptom, excepting the shivering, which was now more frequent. He left home as usual; but at 11 o'clock, A.M. whilst labouring in the garden, he was suddenly seized with excruciating pains in the abdomen, which had continued unabated up to the time of my visiting him, at a quarter past six, P.M.

The skin moderately warm, but he complains of being cold: pulse natural, beating 88; tongue not at all changed from its usual rather coated state; no vomiting, nor nausea; the abdominal muscles as rigid as a board, which prevents my ascertaining any thing by pressure, which neither diminishes nor aggravates the pain; the viscera occupy but very little space,—to use his own words, "my bowels are gone into my back."

The treatment being adopted in ignorance of the real nature of the case, it may suffice briefly to state what it was. Bleed-

ing to ℥xij. (the blood buffed slightly,) calomel, opium, castor oil, fomentations, and domestic enemata: healthy, constipated fæces were brought off by the latter, and he soon expressed himself as much easier, though the abdomen continued as rigid as before. To continue the fomentations, and take at short intervals a mixture of Magnes. Sulph. Træ. Opii, et Aq. Menth. Pip. with pills of Calomel and Antimony. In the morning, about six, he was observed to change much in appearance: a few hours later the pulse 120, weak, but not tremulous; the senses perfect; great calmness; respiration performed without any apparent assistance from the abdominal muscles or the diaphragm, and consequently a short and laborious heaving of the chest; tongue dry and brown; neither hiccup, sickness, nor nausea; the abdomen still hard and painful, the *very reverse of tumefaction*, whether from flatulency or fluid; the bowels have not acted since last mentioned; cornea lucida filmy almost to opacity; the voice lost in a whisper; facies hippocratica.

He died at noon.

Autopsy, 24 hours after death.—The abdomen *very tumid*, and yielding as from fluid within. The right lung congested, and its pleura pulmonalis firmly adherent to the pleura costalis. The omentum covered anteriorly with that kind of yellow deposit termed by Lobstein, kirronosis: a large quantity of turbid fluid in the cavity of the abdomen, resembling in colour the omental deposit. The intestines generally inflamed. The liver and spleen corrugated, and externally of a pale ash colour, but apparently healthy within. The gall-bladder distended with very fluid bile, but it could not be pressed through the cystic duct, which was found to be impervious; but bile was regularly secreted, and passed the hepatic and common ducts. The stomach superiorly, between its small curvative and pyloric orifice, presented an ulcer, which readily admitted the fore finger: this was surrounded by a thick fleshy circle, which did not quite approach the edges of the ulcer, but formed a complete ring beyond it; and from the outer margin of this circle extended a patch of membrane-like substance, some of which was easily rubbed off, leaving the peritoneal coat healthy; but for the most part this deposit or adventitious membrane, for it seemed organized, could not be detached. There was considerable ossification of the abdominal vessels, which, perhaps, as well as the dyspeptic symptoms, influenced the ulcers of the legs, which had resisted the most careful means of cure.

This is another striking instance of the great disparity often found to exist between derangement of function and morbid change of structure. How frequently do we find dyspepties, from only trifling improprieties of diet, suffering acutely, and incapable of exertion; whilst in this case, the man, though often complaining, never ceased to labour even to the day prior to his death!

A few circumstances seem worthy of remark:—1st, That from the moment I first saw the patient up to the period of my leaving him *in articulo mortis*, the abdomen seemed reduced by spasm to a mere handful; but on exposing him for the after-examination, tumidity was particularly striking: it gave, in fact, the appearance of ascites. Knowing the incompressible nature of fluid, how is this to be explained? 2dly, What was this fluid? an effusion consequent to inflammation? and how long had it been present? 3dly, At what period was the ulceration completed? at the time of the accession of pain?

The stomach is in the possession of Mr. Richard Smith, Bristol.

P.S. A young unmarried woman, daughter of the person whose case is related above, is often suffering acutely from pain in the stomach, with a presentiment that it will end like her father's.

CASE OF EXTRAORDINARY CONSTIPATION.

[*Communicated to Mr. Key, and read before the Hunterian Society.*]

My dear Sir,

As I feel confident you will not be uninterested in any peculiarity which may present itself in medicine or surgery, more especially when emanating from and occurring under the immediate eye of one of your own pupils, I take the liberty to send you an account of a protracted

case of habitual constipation, which, perhaps, has been more singular than any to be found in the annals of medicine, and from that circumstance rather than from its intrinsic danger, worthy of being known to the profession, and placed within its records.

My patient, Mary Belmore, aged 73, the wife of a labouring man, requested my advice for "an obstinate costiveness," as she termed it, and gave me the history of her complaint, nearly in the following manner:—

At about 24 or 25 she could not command a daily motion without the assistance of some purgative medicine, which she generally bought at the druggist's, either jalap, rhubarb, or aloes, but even these in the course of time lost their virtue, "unless she took," as she expresses herself, "as much as would poison a dozen ordinary men:" from two days the interval gradually increased, though unaccompanied with any very unpleasant symptoms, except flatulence and occasional dull heavy pain on the right side, (I suppose the head of the colon from her description, and pointing to the spot,) and flying pains from the flatulence, until it became a month; and for the last five years, once in two months, not regular to two or three days. Even before my advice was solicited, a medical practitioner here, just antecedent to the last obstruction, had attended her for the complaint, which had not then been relieved for four months and eight days: she told me that he had been successful in purging her, and that she "must have parted with at least a bushel;" but that she would sooner die than undergo again what she suffered from the effect of the medicine, and that unless I could do something for her, which would act speedily and easily, she would not take any thing: this was about a month after the purged motions, and she has had several since, though not at regular intervals. I sent her a box of pills of calomel, ext. colocynth. ol. croton, and cloves; but whether from the trouble of taking them, or their nauseousness, she neglected their use, and as she had comparatively little or no pain from her complaint, week succeeded week, and month to month, until full *seven months* had passed over without the least discharge from the bowels. Some weeks before her death she had a fall, and hurt her right side (no doubt, particularly the head of the colon,) of which she had complained ever since, the pain gradually getting worse and worse, so that she could not bear the least pressure, and at length was obliged to keep her bed. She died in a few days under the most excruciating pain in the head of the colon from inflammation, which terminated in gangrene of one spot about the size of a crown, from which the feces had escaped, and were found amongst the intestines on the right side.

The friends gave me liberty to inspect the body after death. Its size was like that of a half hogshead, and as protuberant as that of a dropsical person, as hard as a drum, with the skin as tense as it seemed possible to draw it, and quite polished. I made a longitudinal incision from the ensiform cartilage to the pubes, and a cross one from side to side: the muscles were quite absorbed, and the skin and peritoneum perfectly transparent, and each as thin as a wafer, so that they might almost be torn like paper.

The spectacle which presented itself was very singular, but consistent with what might have been expected: the sigmoid flexure of the colon was so much enlarged with flatus at its upper part as to become quite displaced from the left side; but taking its curve as usual on the left side above, the upper part lay completely across the abdomen, like the transverse arch, but upon that part: when it had got to the right side, it again curved towards the left ileum, or rather to the middle of the pubes, and terminated in the enlarged rectum at the bone of the sacrum. Its upper part, which crossed the abdomen, was so distended with flatus as to be nine inches in diameter; and the lower part, which descended to the rectum, and was filled with pultaceous feces, was about ten inches and a half, but where it joined the rectum six inches. Nothing could be seen on first opening the abdomen but this portion of the intestine; a small part of the ileum, where it joins the head of the colon; the enlarged head of colon and the anterior part of the enlarged rectum, the latter seen only because of its enlargement. The rectum was six inches in diameter above, gradually getting smaller towards the anus, which would not more than admit the thumb, though immediately above, it completely filled

the cavity of the pelvis. The head of the colon was about nine inches in diameter, and it, as well as the transverse arch, was filled (I ought to say crammed) with fæces of moderate consistence, having only a few scybala, not sufficient to have produced irritation as a cause of the prevailing inflammation. The stomach, though an immense cul-de-sac, and appearing as if it had been much distended, was more than half empty, and the duodenum, jejunum, and ileum quite so, and their coats perfectly healthy, only thickened in their muscular and mucous structures, as were also the large intestines. The fæces were not inordinately offensive, considering the length of time they had remained in the bowels, nor, excepting the rectum, were they near so concrete as might be expected; but in this gut they were literally as hard as wood, and would require the chisel or hammer to break them in pieces.

Her appetite had always been tolerably good, nor did she refrain from any common diet that presented itself, though generally she lived on fat pork and vegetables.—With much respect,

Your's most sincerely,

S. STANILAND.

IMITATIVE EPILEPSY.

To the Editor of the Medical Gazette.

SIR,

THE following cases of imitative epilepsy were recently brought to my recollection. Should they possess sufficient interest, you will perhaps afford them a place in your journal.

Feb. 1829.—Nathaniel Webb, a labourer in a neighbouring village, about forty years of age, was seized five months since with epilepsy, as it appeared, from grief at the loss of his wife, as well as anxiety at having been left with a numerous and dependent family. The paroxysms became frequent, exceedingly violent, and probably maniacal; and a strong healthy young man (Shell) was hired to look after him. At the end of seven weeks this person, who had kept his station night and day, became himself epileptic in a very high degree. An acquaintance of his (Newman), of equally robust make, but some years older than himself, occasionally visited the parties. In a fortnight from his first visit he also was seized with similarly violent attacks. On the 10th of February, 1829, they both applied at the hospital for relief; but, though coming from the same place, and on the same errand, they avoided each other with the utmost caution—one arriving about an hour after his friend.

I spare you their cases in detail, which, except from the singularity of their origin, were altogether without interest. The treatment consisted of cupping and purgation, and they were soon well. It is believed that Webb, the man originally affected, also recovered.

So stood the case up to September 1829, when Webb came to the hospital for advice about another complaint, never making the most remote allusion to his epilepsy. When pressed, however, he said that he was not cured, but that he was occasionally attacked by the fits, and that both Newman and Shell had suffered a relapse, but that the latter had had no attack since July. This man (Webb), whose complaints were trifling, soon became irregular in his attendance; and I was unable to get a sight of either of the younger men, or to procure what I conceived to be a true history as to particulars, though I had not the slightest doubt as to the leading facts.

Feb. 24, 1832.—A patient, from Box, applying at the hospital this day, reminded me of the above statement. He says that both the young men are now well, but speaks less positively of Webb. He confirms the whole of their account.

Many cases resembling the above have probably been recorded, but the only one which occurs to my recollection at present is the following, alluded to by Baglivi, who says, (lib. i. cap. 14.) "Vidimus, anno 1690, in Dalmatia juvenem gravissimis correptum convulsionibus, propterea quod inspexerat solummodo alium juvenem, dum epilepsia humi contorquebatur."

Finally, Mr. Editor, I feel bound to apologize for occasionally troubling you with these unadorned and any thing but elaborate cases: but what they might gain in polish they might possibly

lose in accurary; or, more probably, if much *filing* were necessary, be passed by altogether. One word fixed on at the moment is, according to Gray's phraseology, "worth a cart load of recollections;" and in reports of this sort, it has always struck me that the less of lucubration that accompanied them the better. Without connexion, and without pretence, they may yet aspire to a certain degree of consideration, so long as they are under the guidance of nature and of truth.

"The Jews," it is well said, "were commanded to build their altar with stones unhewn and untouched by any tool; and, in like manner, the best materials for natural knowledge are the plain facts themselves, just as they come from nature: he who pretends to new model and polish them, in order to their being adapted more perfectly to his system, has utterly polluted them, and made them unfit for the altar of truth."

I am, sir,
Obediently yours,
C. H. HARDY, M.D.

Bath, Nov. 1832.

PROCESS FOR OBTAINING CONIA.

To the Editor of the Medical Gazette.

SIR,

A process was published in the last edition of Dr. Ure's Dictionary, for the preparation of a peculiar alkaloid from conium maculatum (copied from a Continental journal); upon the repetition of which I was unsuccessful in obtaining it. This induced me to carefully repeat the experiment, and I find that no conia can in this manner be procured; but by the following process it may be prepared with great ease, and in a state of purity.

Digest the fresh leaves of conium maculatum in alcohol, and set aside for some days and strain the mixture; boil the alcoholic tincture for a few minutes, and when cold filter. By this operation a solution is obtained of malate of conia with extractive and some salts; decolourise with animal carbon, again filter, and add to the clear liquor a solution of carbonate of soda. A precipitate of carbonate of conia will fall, which must be dried and dissolved in acetic acid; ammonia will now throw down conia quite pure.

Conia, as thus obtained, is a powder perfectly white, slightly soluble in water, and very soluble in alcohol and æther. It turns red litimus paper blue, and combines with acids, forming in some cases crystalline compounds, in others gummy masses. When heated with nitric acid, a brownish-yellow solution is formed, and, by evaporation, oxalic acid is obtained. When dilute nitric acid is used, a nitrate is obtained in fine needles.

When attempting to prepare conia according to the German process, after obtaining the spirituous extract and adding water and protoxide of lead, a lamp heat was applied: a dense, fœtid, suffocating vapour was given off, smelling intensely strong of hemlock, and producing a violent sensation of asphyxia; while, on the surface of the fluid, there appeared films of an oily matter. This operation was repeated in an alembic, and the vapours were condensed in a cool receiver. I thus obtained a volatile oil, very inflammable, and smelling powerfully of hemlock.

By proximate analysis, I find the leaves of conium maculatum to consist of, 1. Malate of conia; 2. A fœtid volatile oil; 3. Chlorophylle; 4. Resin; 5. Fœculin; 6. Albumen; 7. Lignin; 8. Acetates of potass and ammonia; 9. Malate of lime. The ashes contained traces of, 1. Chloride of sodium; 2. Protoxide of iron; 3. Magnesia; 4. Lime.

I am, sir,
Yours obediently,
GOLDING BIRD.

44, Seymour-Street, Euston-Square,
November 2, 1832.

NEW VAGINA SPECULUM.

To the Editor of the Medical Gazette.

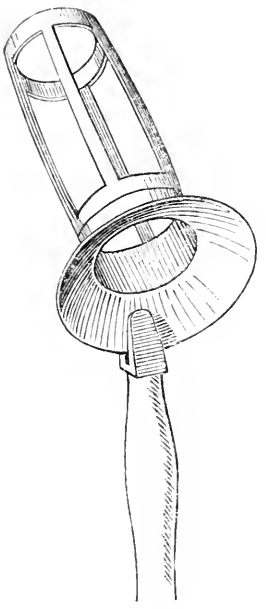
SIR,

I send inclosed a sketch of a vagina speculum which I have had constructed, and used with much success. It is made of pewter, and possesses the very important advantages of cheapness and efficacy, giving a perfectly unincumbered view of the sides of the vagina, as well as the os tincæ. It is also very va-

luable in examinations of the rectum, where a side view alone is requisite. If any of your readers should feel inclined to give it a trial, they may procure the instrument, of different sizes, at Mr. Thompson's, surgical instrument maker, Windmill-Street.

I am, sir,
Your obedient servant,
J. Thos. Elliot.

49, George-Street, Portman-Square,
Nov. 13, 1832.



MR. MAYO ON THE USE OF IODINE IN SYPHILIS.

To the Editor of the Medical Gazette.

Sir,

It is difficult to understand upon what principle remedies are thought to be more efficacious at their first introduction to professional notice, than they are found to be afterwards; but of the fact there is no doubt, and therefore it is with considerable misgivings that I venture to express a conviction of the utility of iodine in a particular class of cases, of which I will give examples.

It is, indeed, well known, that the outward and inward use of this remedy will in many instances reduce the size of a bronchocele: of this I have had, in common with others, repeated experience in my private and hospital practice. Iodine has likewise been supposed to have a corrective influence in strumous diseases: I cannot say that my own observations corroborate this opinion. In one case only of this description that I recollect did it appear to be beneficial. A patient, about twenty-five years of age, had an enlarged lymphatic gland, or mass of glands, in the neck, which certainly has been reduced to a third of its size, and is likely to be entirely dispersed during the exhibition of iodine. The gentleman, to whose case I refer, I attended with Mr. North: he had previously been seen by Sir Astley Cooper and by Mr. Brodie. The tumor happened to be placed on the carotid artery, and it was upon the patient's mind that it might be an aneurism.

The disorders in which I wish to point out the efficacy of iodine, are the consequences of syphilis; emaciation of the frame, with ulcers of the skin; ulcerated throat; inflammation of the bones or periosteum—occurring in patients to whom mercury has been given. The two first cases which I shall narrate, have been already noticed in the hospital reports in the London Medical and Physical Journal.

I. Ino. O'Shaughnessy was admitted into the Middlesex Hospital in January 1830, having contracted the preceding autumn chancre with bubo, for which he took mercury, followed by ulcerated throat and leprous eruption. At his admission there were several large leprous spots on his limbs and body; a very large superficial ulcer on the instep; another on the shoulder. Sarsaparilla, with liquor potassæ, was now given, and under the use of this medicine, and of various local applications, the ulcer on the instep healed. But the malady gained ground. The limbs were covered with lepra alphoides. Several of the spots of lepra became tubercular, and in place of the thickened white patch of desquamating cuticle, a crust formed with an ulcer below it. There were many of these ulcers on the limbs and body: the forehead and face were covered with them. The lips, the ala of the nose, the eyebrows, were equally involved in ulcerated blotches. The patient suffered from burning heat of the body

and face, and the ulceration of the lips produced profuse ptyalism. The bones were not affected; but there was pain on moving the joints of the legs, and a small depôt of serous fluid formed in the calf of the right leg. A variety of remedies were used in succession. Sarsaparilla, combined first with liquor arsenicalis, then with the oxymuriate of mercury; the decoctum smilacis asperæ; the blue pill, so as slightly to touch the gums; bark, with the nitric and muriatic acids; the strong nitric acid—a drachm a-day. All these remedies in their turn were of a slight but temporary benefit, and produced for a short time a seeming improvement, (after which the patient fell back,) with the exception of the blue pill and the nitric acid. Both of these were discontinued in ten days after their first use, no amendment, but an aggravation of the symptoms, having ensued.

At this period (December 1830,) M. Magendie, who accidentally saw the case, recommended me to try iodine with my patient, which I accordingly prescribed. The effect of the remedy after a few days' use was very striking; the skin became less red and heated, several of the crusts separated, and the ulcers put on a healthy appearance. In a month the patient had made a great amendment. But now the improvement ceased; I therefore discontinued the use of the remedy; when the patient became worse, and the cutaneous disease increased. After a fortnight he resumed the medicine, with equal temporary success. In another month a second period occurred in which the disease was stationary. He then discontinued it, to resume its use again in a fortnight. Through these means, in five months he recovered his strength and health; but at intervals a few blotches still reappear upon the face, upon which he has recourse to iodine with success.

II. John Saxon, ætat. 31, was admitted with symptoms which followed a venereal sore and a course of mercury. In 1828, the scalp upon the forehead became at two points puffy and tender, but not discoloured: it soon became red and broke, and then for many months the face was disfigured in the following manner:—Two or three ulcers formed on the forehead, eyebrows, and bridge of the nose, round which the skin was red and thickened; and these spread, after healing at the point where they began, over a fresh surface. With this patient every remedy enumerated in the preceding case was tried; every change seemed temporarily useful; and after each amendment the patient fell back. I prescribed iodine in this case at the same time that O'Shaughnessy commenced it. In this case the amendment was more rapid, was uninterrupted, and the patient has been several months perfectly well.

III. A young gentleman, ætat. 25, returned from India last summer, with a constitution broken by syphilis and mercury. The soft palate had been nearly destroyed, but its remains adhered to the back of the pharynx, leaving a larger opening than common in such cases towards the nostrils. The surface of the pharynx seen at this opening had been ulcerated, and was not yet healed. Upon the right of the forehead, and on the left cheek, there was puffiness and tenderness of the periosteum. One testis had suppurated, but had healed. The other was greatly enlarged, and although the skin had not broken, it threatened to run the same course as that first affected.

This state of things had followed upon primary venereal sores, leading to ulcerated sore throat and leprous blotches upon the skin, for which the patient had taken more than one course of mercury in the course of the two preceding years. During the first two months after his return, this patient took in succession sarsaparilla with liquor potassæ, sarsaparilla with Plummer's pill, quinine with sulphuric acid. These means produced no beneficial result. He became more extenuated, with night sweats and loss of appetite. The tender spot on the forehead became red, and then dropped into a circular ulcer of the size of a sixpence. The testis suppurated, and threw out a large scrofulous fungus. At this period, and when the patient was certainly becoming worse, I prescribed iodine. He has continued to take it to the present time. Shortly after beginning it, a visible improvement took place in his health, and in succession the tenderness of the cheek bone went away, the ulcer upon the forehead healed, the fungus of the testis shrunk, and he is now completely recovered.

IV. Thomas Summers, æt. 29, was

admitted into the Middlesex Hospital on the 18th of September last. The end of the nose was swollen and red, and the inner border of both nostrils, together with the lower edge of the septum nasi, were ulcerated. He complained of pains in his limbs, and both tibiæ were tender and slightly swollen for the extent of several inches.

Upon inquiring into his history, the patient stated that he had been during the last five years once in St. Thomas's hospital, and once in the Lock; on the first occasion for chancre, with eruption on the skin, on the second for an ulcer at the roof of the mouth, with pains in the shin bones. In both instances he took mercury, and recovered. The account which he gave of his present illness was, that three or four months ago the lower edge of the right nostril became inflamed and ulcerated, and that the affection has been gradually extending itself. He had taken mercurial pills before he came into the hospital, and his gums were a little swollen and red: I therefore ordered this remedy to be continued. But as I observed after a few days that the patient did not improve, I substituted for ten grains of blue pill in the twenty-four hours, the decoction of sarsaparilla with liquor potassæ. The patient improved on this change, but in no great degree, and then the complaint seemed stationary. On the 22d of October I prescribed iodine; in a week he was visibly better. The ulcers of the nose have now entirely healed, the redness is gone, and the nodes have disappeared.

V. John Palmer, æt. 39, was admitted into the Middlesex Hospital, Oct. 12, 1832. Having previously twice had primary venereal affections, which had got well with mercury, three months before his admission he contracted another ulcer upon the penis. This healed under the use of a few mercurial pills, which he obtained at a dispensary.

What he now laboured under was ulceration of both tonsils, the right being principally affected. Upon the calf of the left leg were two painful phagedenic ulcers; one an inch in diameter, the other two inches. He swallowed with great pain and difficulty, his tongue was furred, and he had no appetite. He had taken some pills before his admission, and the gums appeared slightly touched with mercury.

From the 12th to the 22d of October, during which he used, as an application to the throat, first the gargarisma aeruginis, and afterwards fumigation with cinnabar, he became gradually worse. The ulcerated throat assumed an ashen hue, threatening to slough: I then prescribed a gargle containing chloride of lime and iodine. The patient in two days was sensibly better, and in three weeks, being well enough, and having urgent business, he left the hospital, his throat being quite healed, and the ulcers upon the legs having put on a healthy character.

The form in which I gave iodine in the preceding cases was the following:

℞ Iodini gr. ss. ad gr. j. ad gr. iss.; Hydriodatis potassæ ʒss., Syr. papaveris ʒss.; Aquæ. menth. ʒviij. ad ʒx.

I am disposed to believe that the iodine was of service in these cases, and that the recovery of my patients was more than an accident; and I anticipate that this medicine will form an useful tonic and alterative, by the side of sarsaparilla, combined with alkalies, or with the mineral acids, when used in constitutions worn out with syphilis and syphiloid disease, and where mercury is contraindicated. In giving iodine it is necessary carefully to watch its effects, and to discontinue it temporarily, resuming its use afterwards in smaller doses, if it produce pain and heat in the stomach, or sickness and purging.

Your obedient servant,
HERBERT MAYO.

OBSERVATIONS ON SOME OF THE REMEDIES PROPOSED IN CHOLERA.

EFFICACY OF SUGAR OF LEAD*.

With regard to cholera, it seems now in the highest degree desirable to arrange the vast mass of evidence contained in the numerous journals of the day, so as to discriminate all the circumstances of those cases which have been benefited by a particular remedy,

* The following paper is from the pen of a highly respectable practitioner, at a watering-place which cholera visited, though its existence there was not generally admitted. He desires his name to be concealed, and we only attach initials; but our readers may trust to the facts.—E. G.

and thus reconcile the apparently opposite modes of treatment, by pointing out that condition of the disease in which each may be successfully adopted. We can have no premised right to believe one who tells us he cures a very large proportion of his patients by calomel, opium, and other stimulants, in preference to another who affirms himself perfectly successful with salines. If their cases are equally well authenticated, he is as worthy of belief who debars his patients from all fluids, as he who drenches their stomachs with cold water—he who gives kino, and he who administers croton oil; or we must disbelieve all. As the supposition, that our profession contains so many men willing to give gratuitously false evidence, is absurd, we must attempt to account for the recorded success of such opposite methods of cure.

We are told of cases in India where the person, apparently in health the minute before, suddenly became cold, pulseless, and dropped down dead; the poison acting, it is probable, in a concentrated dose, and imitating the effect of the Upas antiar, and strong infusion of tobacco, by paralysing the heart. In doses more dilute it has a proportionably less influence on the heart, and causes vomiting, purging, suppression of the urinary secretion, and of the secretion of the liver, or it prevents its passage into the duodenum. All these symptoms are subject to the modification of local causes, and individual constitutions, which may give predominance to one over the others,—as we know that persons of a relaxed habit are more liable to the diarrhœa of cholera, while in some districts purging, and in some vomiting, is regarded as the chief symptom. These effects of the poison aid its deadly action, by becoming of themselves sufficient causes of destruction to the patient. Spasm may be so violent as to exhaust the nervous energy; the peculiar vomiting and purging may render the blood unfit to maintain life, by depriving it of its salts and water, even though the ultimate cause of the disease be thrown out of the system by these means; and we too frequently observe the deleterious effects of charging the system with bile, urea, or their elements, when the secretions of the kidney or liver are suppressed or detained. In a word, any of the effects of the poison may be the immediate cause of death, according as each predominates. Surely, then, a person writhing in the agony of a violent spasm, without saline purging, should be treated differently from one lying prostrate devoid of pain, but with insensible draining of serum. Would it not be absurd to give a patient a mustard emetic, whose already irritable stomach was discharging copiously a component of the blood highly necessary to life; or to give nothing but croton oil to one purging salt and water in abundance, and already cold and pulseless, where, if the remedy should reproduce the secretion of bile, the blood is left in a state unfit for circulation? Would any one think of debarring a patient from water who could keep it on his stomach, or allow the action of vomiting to exhaust one whose stomach would not retain a drop? Yet all these opposite modes of treatment might have been suited to the cases to which their inventors first applied them. The mustard emetic may in some cases have succeeded, by rousing the action of the heart, when the poison was paralysing that organ; and provided the blood was but slightly deteriorated from loss of its serum, these patients might recover. Croton oil may serve to excite the biliary secretion, or relieve a loaded stomach, as in the case of the gentleman who recommends it; but either of these remedies I should be cautious in exhibiting in cases with purging. Bleeding, mustard poultices, and small doses of calomel and opium, may be useful in the spasmodic form of the complaint; and cold water may be both allowable and useful where there is purging, if it do not excite an exhausting irritability of the stomach. But will any of these remedies restore to the blood the salts of which it has been deprived by the vomiting and purging? We must, therefore, receive accounts of any universal remedy, for all stages and symptoms of cholera, with suspicion.

In my own practice I at first used calomel, opium, and mustard poultices, then small and frequent doses of calomel and opium, in combination with the saline treatment, and had certainly more success with the latter plan. But I soon found that the treatment must vary with the circumstances of the case. On analysing the evacuation according to the directions of Dr. O'Shaughnessy, I found one patient was passing salt at

the rate of a drachm in the hour, while the stomach would not retain the stronger saline medicine. In short, the purging was draining the system much faster than the saline fluid could be replaced; and my task, like that of the Danaides, was useless. It seemed to be the first indication to arrest this purging. I tried catechu, kino, and the usual astringents, but the stomach would retain nothing of any bulk. In this emergency I met a patient who, a short time before, had had painter's colic, and given me infinite trouble to open his bowels; and it occurred to me, that if I could induce a temporary attack of that disease in one of my patients, and thus correct the prominent and fatal symptom, I might be able to cure her. I therefore administered some acetate of lead directly. This has been prescribed by Dupuytren, but not in a manner sufficiently impressive for me to have had recourse to it had it not been for this case of painter's colic: I then used it on his authority. My patient took 7 grains, in repeated doses, in a few hours, and I had the satisfaction to find the purging stopped and the stomach (either from the action of the lead or not) become quiet. In other respects she was no better; the voice was a whisper, and the coldness and lividity of the skin, the restlessness and suppression of urine, continued. I now gave Dr. Stevens's saline mixture in large doses, with plenty of cold toast-water. All was retained, there was no further purging, and I had the inexpressible gratification to find her convalescent; in short, she recovered without the consecutive fever. This was on the 20th of July. I have since had several similar cases, quite as successful. In some, where vomiting was the most urgent symptom, I have at first forbidden the use of fluids, and given carbonate of ammonia, in doses of 5 grs. made into pills with crumb of bread; then effervescing powders, with oil of peppermint and a small quantity of water; and, when the stomach was quiet, plenty of toast water, &c.

I must also mention another method which occurred to me in the case of an infant at the breast, whose mother was one of the patients treated with lead and salines. It was a marked case. The child, which I had seen the day before plump and healthy, was cold and shrivelled, and had vomited and purged a large quantity of the peculiar rice-water fluid. I immersed it in a strong hot solution of salt for half an hour, and, on taking it out, it was quite red and amazingly plump. It retained its mother's saline mixture on its stomach, and got well without any other medicine. I have since, in all cases where the introduction of salt into the system seemed indicated, used frictions of strong hot brine over the abdomen and chest, instead of the mustard poultice. This child passed, after its recovery, the most fœtid motions possible.

I have seen several recover under calomel and opium, but these were cases in which cramp was the worst symptom; and this, although it appears most alarming, is in reality far less formidable than the passive purging which people seem most inclined to make light of. As far as my observation goes, I have seen none recover after such purging as that of the woman abovementioned, except under the saline treatment, modified as I have explained.

Of course I should hold salt and water inadmissible in a case with violent cramp, a full pulse, and no purging, even were I sure that it was the spasm of cholera; but I should rely on a small bleeding, a mustard emetic, and a dose of calomel—as my experience in such cases would warrant me.

I attended an old man in whom the cramp was excessive; he had no vomiting or purging, but his bowels had been relaxed the day before. He was bled to twelve ounces, took several doses of calomel and opium, and was fomented with the hot brine. He was now relieved, having a natural stool the day after, and appearing quite well, with the exception of soreness in his limbs. At six the next morning purging came on, and at ten, when I happened to call, (for they did not send, though I met three messengers when he had cramp,) he said his bowels had been acted on at least thirty times, and the fluid was beginning to run from them without his knowledge; his skin was getting blue and cold, and his pulse was very feeble. I immediately supplied him with four pills, each containing two grains of acetate of lead, one of which he was to take directly, and one every quarter of an hour after, if the purging continued. He took three, did not vomit, swallowed a pint of Dr. Stevens's mixture in a few hours, and recovered without the consecutive fever, although an habitual

drunkard. This case requires no comment.

I do not remember to have seen this consecutive fever, as it is termed, except after severe serous vomiting and purging, and when the salt was not replaced. If this observation be confirmed, it will complete the chain of evidence that the consecutive fever is not a necessary consequence of the first cause of the disease, but of some of its effects.

I have, of course, had unsuccessful cases. Altogether, without reckoning the lighter though well-marked cases, but only those which became collapsed, I have treated thirty-one; out of which ten died, and twenty-one recovered. Of the ten which terminated fatally, two died before the remedies could be administered, and four before I adopted the views I have endeavoured to explain to you. I have injected the veins four times: once successfully in a very desperate case, when the patient was all but dead; once fairly without success; and in the other two the patients were drunkards and had taken opium, so that they should not be received into the account. I do not hesitate in saying that the proportion of deaths would have been very different but for the saline treatment; without it, the lead, ammonia, &c. I feel certain would have been of little use to those who recovered; and, for one, I give my full quota of the thanks which I think are due from the profession to Dr. Stevens, for calling its attention to the absence of salt from the blood in cholera, and opening a new field of investigation to others.

In order, then, to rescue the treatment of this disease from the empiricism which more or less hangs about it, it is highly desirable to class the symptoms, as much as possible, with reference to their causes, that the precise circumstances may be distinguished in which benefit can reasonably be expected from this or that proposed mode of cure.

To effect this, a more complete chemical physiology of the blood is requisite, or we shall in vain attempt to grasp the subject: for instance, were it known, by direct analysis, if any and what gases exist in healthy arterial blood, chemistry might throw light, by a similar analysis, on the pathology of arterial blood in cholera; which, I believe, has not yet been examined.

I have uniformly observed, as in the case of the child, that if, under any treatment, the patients recovered, in some period of their convalescence they have passed stools of an unusually offensive character: would it not be well, as the serous secretions have been examined, to question these also, with a view to discover whether the peculiar ultimate cause of the disease be not thus eliminated from the system?

Small animals might be exposed to their influence in closed vessels, and many other experiments of promise might be suggested. Could we make it probable that, by any of our analyses, we had detected the poison itself, we might endeavour to get a direct antidote to it, as we neutralize the effect of hydrocyanic acid by ammonia, and that of the acetate of lead by the alkaline carbonates. At least we could ascertain whether any of the remedies hitherto recommended possessed a just claim to the title of antidotes.

H. G.

GRAPHIC DESCRIPTION OF CHOLERA IN 1786.

To the Editor of the Medical Gazette.

Sir,

If beautifully concise and correct description have any charms for you, I have no doubt you will endeavour to find room in your journal for the following account of cholera, extracted from the preface of the fourth fasciculus of Retzius' "Observationes Botanicæ," published at Leipsic in 1786. It is an extract of a letter from König, an Indian traveller and botanist, to his friend in Germany.

Your obedient servant,

M.

London, Nov. 1832.

Scripsit (König) in ultimis litteris, die 16 Octobris, 1782, Tranquebariæ datis.—"Nuper iterum morti proximus fui; morbo enim diro, quem dysenteria apoplectica appellare fas est, tenebar, quo me mortuum jam in urbe rumor spargebat. Sanitatem redidit clementissimus Deus. Integer tamen mensis ante perfectam restitutionem transiit. Morbi cursus hic est: diarrhœa corripitur æger cum elastica quasi excrementorum ejectione, dein sequuntur ejusmodi dejec-

tiones, quæ nihil nisi humorem lymphaticum clarum continent. Manus mox frigent cum pedibus; manuum musculi contrahuntur, et hæ æque ac facies flavidum glutinosum mucum transudant. Pulmones angustantur; vox ranca vix adstantibus percipienda; alii timore perculuntur, alii indolentes videntur; pulsus in omnibus extremitatibus deficit, et tantum ad arteriam carotidem observatur quamvis irregularis. Nonnulli jam vomunt, ungues lividi fiunt, et diri spasmi brachia et suras corripiunt cum clamore ægroti. Hæc mors sequitur sine insigni convulsivo motu. Cursum hunc sequitur morbus qui sæpe intra semihoram terminatur, nonnunquam sex ad octo horarum spatio absolvitur. Qui remediis sublevantur idoneis ad nyethemi spatium illum protrahere possunt; pauci sibi relicti convalescunt. Hunc ego morbum periculosissimum vici et sospes prolixe descripsi."

CHOLERA SPREADING BY CONTAGION.

To the Editor of the Medical Gazette.

Sir,

The following statement relative to the effects of contagion in cholera may be relied on. The town had been visited by the disease, but for fifteen days not a single case ensued, when, on the 17th September, the body of a man named Waldron, who died of cholera near Dublin, was brought for interment, and delayed for a couple of hours, the coffin being meantime removed into the chapel. Three of the men who carried it were seized with cholera, and are dead; the first was attacked on the 19th, and the others within the week. The wife of one of the men was severely attacked, but is now recovering; two boys who got into the hearse to play are both dead; and the sister of one, who attended him, and washed his clothes, also fell a victim to the disease.

Since the return of this disease there have been thirteen cases, and eleven deaths. As yet, all who have been attacked since Sunday, 17th September, were either the relatives or friends of the deceased, or assisted at his funeral.

I am, sir,

Yours very respectfully,

W. S. M'Evoy,

Surgeon, Balbriggan and Skerries Dispensary.

Co. Dublin, Oct. 5, 1832.

STUDY OF ANATOMY—VALUE OF EXTENDED COURSES.

To the Editor of the Medical Gazette.

"Res mere anatomicæ frigidæ sunt et jejunæ."
Weitbrecht.

Sir,

It was with much pleasure I noticed that you had devoted a portion of your columns to the advocacy of the advantages resulting from the practice of giving extended courses of lectures on those branches of medical science which, from their great practical utility, are entitled to the fullest consideration.

Among these branches anatomy and physiology stand pre-eminent, and confessedly demand from the student a large share of attention. In Scotland, in Ireland, in the various celebrated continental schools, and in those of America (so far as I am informed), these subjects are treated of in courses of six months' duration (an hour being the period of time allotted to each lecture); but in the schools of this city, and of the provincial towns of England, a little more than three months is deemed sufficient time to devote to them. It may not, therefore, be unreasonable to question the utility of a system so limited in its adoption.

The great evil of "three months' courses" appears to me to arise from the necessity which they inflict upon the teacher, of passing over in a superficial manner many very important parts of anatomy; he is compelled to generalize to a considerable extent in his descriptions, and to adopt a style so loosely popular, that the student is apt to imbibe notions vague and without precision. This general, or, as it has been called, "coarse" kind of descriptive anatomy, almost necessarily engenders a degree of inaccuracy, which, though perhaps not sufficient to be practically injurious, ought to be scrupulously avoided; it likewise induces the additional evil of leading the student to attach but a minor degree of importance to minute anatomical investigations. Such a minute knowledge, he thinks, he never will have occasion for in practice, and unless he has reason to expect that he will be called on to exhibit it at an examination for his diploma, he sees no benefit likely to result from the possession of it. Yet I much fear, that the *secret* history of medicine could reveal not a few fatal consequences of the neglect of acquiring

this knowledge. The records of medical biography, as well as daily observation, fully indicate to us how much the example (even more than the precept) of the teacher has to do with forming the taste, and directing the pursuits, of the pupil. But for the guidance and direction of an able and scientific brother, the genius of a Hunter had been lost to medical science; and there are many living instances to attest how much was effected by the example of that Hunter. Under the presiding influence of Desault the master-spirit of Bichat was fostered, till it shone forth with that effulgence which is still reflected by the many illustrious pupils of his school. The inference I would derive from this fact is obvious; it is greatly in favour of the adoption of the system which allows an extended period for the minute and philosophical treatment of anatomy and physiology. The student estimates the importance of these sciences, or portions of them, by the degree of attention bestowed on them, and time devoted to them, by his teacher; and in his own cultivation of them instinctively imitates his example.

These remarks I would offer with diffidence to your numerous readers, more especially to those who are engaged in teaching anatomy. They are the result of consideration, and of a strong conviction in favour of the system which I would advocate; but are submitted in that spirit which prompts me to conclude in the words of the poet—

"——— si quid novisti rectius istis
Candidus imperti; si non, his utere mecum."

I have the honour to be,
Your obedient servant,
R. B. Todd.

5, Hart-Street, Bloomsbury,
Nov. 19, 1832.

REGISTRY OF APOTHECARIES.

To the Editor of the Medical Gazette.

Sir,

Will you be so obliging as to publish in your valuable journal the following letter to the Court of Examiners of the Apothecaries' Company?

Yours respectfully,
An Old Subscriber.

To the Court of Examiners of the Apothecaries' Company.

Gentlemen,—I beg leave to suggest to you the importance of allowing apothecaries who were in practice previously to August the 15th, 1815, to be registered at the Hall, allowing such registration to be valid evidence of their being legally authorised to practise and to take apprentices. I was a member of the Royal College of Surgeons, and in general practice for myself, in 1814, and until after the 15th of August, 1815; soon after which I moved, and am now upwards of a hundred miles from the place in which I commenced practice. It would be very inconvenient for me to produce legal evidence of my qualification every time I took an apprentice. The same difficulty would present itself in the attempt to recover by legal process a professional debt; and without some such arrangement, the legality of indentures under certain circumstances, as the death of a practitioner, or his removal to a distant country, could not be ascertained by you. It would be an act of justice to the profession, and would guard you against many impositions which are too frequently practised.

I have the honour to be, gentlemen,
An Apothecary of the
Olden Time.

London, Nov. 12, 1832.

CEREBRAL COMPRESSION.

To the Editor of the Medical Gazette.

Sir,

I send you the following case of sero-sanguineous cerebral compression, considering it important both in a pathological and medico-legal point of view.

I remain
Your obedient servant,
R. R. Robinson,
Surgeon to the London Dispensary.

Cooper's Row, Oct. 1.

June 15th, 1832.—A young man, between 22 and 23 years of age, of strumous constitution, and who for the last two years has been labouring under thoracic disease, of which he has only lately got the better, quarrelled with his brother last evening, by whom he was struck on the head; after which he fell, and in falling again struck his head against the wall: he was not stunned, nor did he feel unwell afterwards: even this morning he seemed quite as usual; called upon me about ten concern-

ing his mother, whom I was at the time attending, but made no complaint; about an hour afterwards he turned pale, cold, and sick; fell down suddenly, and was senseless for a quarter of an hour. When I saw him between two and three he was lying in a state of stupor, though when spoken to he answered questions correctly; had headache; pupil dilated, but contracted on exposure to light; unable to sit up in bed; skin cold; has vomited large quantities of bile; and has just had a motion, passed (according to his mother's account) involuntarily; pulse small and feeble.

V. S. ℥viij. syncope. Hirud. viij. temporibus. Lotio frigida capiti adraso. Cal. gr. v. Pulv. Jalapæ gr. xx. statim.

8 P.M.—Blood drawn from arm free from buff; leeches have bled freely; head relieved; large quantities of yellow bile vomited; heart's action regular; tongue clean and moist; thirst urgent; pulse soft; skin warm.

Mist. Effervescent. quartis horis. Repetatur lotio.

16th, 2 P.M.—A little sleep; delirious through the night; quite sensible now; constantly vomiting large quantities of bile; pupil contracts upon exposure to light, of which there is a slight intolerance; one motion; feels a weakness of left arm, (complained of numbness and pain in this arm a fortnight before the accident, of which I was not informed until a day or two before his death); pulse regular, soft, 84; tongue clean; one motion; hair has not been taken off.

Repetatur lotio capiti.

8 P. M.—Much as before; rather more pain of head.

Hirud. x. temporibus. Cal. gr. ij. Ant. Tart. gr. ¼ 3a quaque horâ. Repetat. lotio.

17th.—Little change.

Applicentur hirud. xij. temporibus.

18th.—No motion; urine free; skin hot and dry; pulse bounding, 73.

V. S. ad ℥xx. partial syncope; head immediately relieved.

Cal. gr. iij. statim. Magn. Sulph. ℥ij. Ess. Menth. P. gtt. iij. quartis horis. Applicetur glacies capiti.

11 P.M.—The first portion of blood drawn from the arm, about ℥xviij. not at all buffy; the remainder (℥iij.), in second cup, completely so; crassamentum flat; head was for a time relieved, but about half-past seven he was reported to have had a fit. He was cupped upon the neck to ℥iv. and before the operation was finished, his recollection and sensibility returned.

Repetantur pilulæ, lotio, et hirud.

19th.—Symptoms somewhat mitigated.

Repetantur hirudines viij. Cal. gr. ij. ter die. Mist. Salinæ ℥iss. 6tis horis.

24th.—Continued to sink gradually, having headache, convulsions, and paralysis of left arm. He died about eleven this day.

DISSECTION.—Muscles exceedingly rigid.

Head.—Scalp quite pale; bones of the cranium curiously united at the sutures, in some parts overlapping each other, so as to form tuberosities, with corresponding depressions. Dura mater very firmly adherent to the skull, and very much congested: that portion covering the right hemisphere much more prominent than the other; of a dull yellow brown colour, not possessing, as the other side did, its original silvery hue. This was found to be owing to blood extravasated underneath it, over the whole upper surface of the right hemisphere, partly solid, partly fluid, by which this hemisphere was much compressed. Some of the coagula adhered very firmly to the interior of the dura mater. The blood (in all ℥ij.) appeared to have proceeded from a vessel of the arachnoid or pia mater, ramifying over the posterior and upper part of the right hemisphere, which was slightly lacerated in this situation, and contracted around it; while all the other vessels were very much congested with blood. The whole surface of the right hemisphere had a deep red tinge, which was easily wiped off; but upon cutting it, there were more numerous red points than on the opposite. Structure of the brain rather soft. Upon opening the left ventricle there was a copious flow of transparent serum, altogether amounting to full four ounces, which upon farther examination was found to have flowed from a cavity nearly as big as the clenched hand, formed of both ventricles extended, and united into one by the obliteration of the septum lucidum, and which had the appearance of long standing disease. Some serous fluid tinged with blood in the base of the brain and serum copiously flowed from the theca vertebralis upon holding down the head.

Thorax.—Some appearance of old disease, probably unconnected with the cause of death.

Abdomen.—The liver and both kidneys (the left decidedly more so than the right) congested; mesenteric glands enlarged, and some of them hard. All the other abdominal viscera healthy.

REMARKS.—Upon perusing this case, attention seems naturally directed, 1st, to the state of the brain, in which I think three diseased actions may be recognized.

Hydrocephalus Internus, which had probably been existing some time, and which it is reasonable to suppose might have owed its origin to the congestion which must have taken place not only in the brain, but in every other organ, from the impeded circulation, the result of the thoracic disease. That fluid existed in the brain prior to the accident I am led to believe, from the numbness of the left arm, experienced a fortnight before the accident; from the conversion of the two ventricles into one, by the slow process of extension, and not by laceration; and from the absence of distinct marks of inflammatory action.

Concussion, which might have increased the quantity of fluid already existing, might have still further stretched and disturbed the cerebral substance, and might have bruised, but I do not think it ruptured, the vessel, that ultimately bled; the symptoms of which, temporary insensibility, convulsions, sickness, &c. did not show themselves till the following morning, and then came on very suddenly.

Compression, from extravasation of blood, which did not, I think, begin till the fourth day, as the sickness stopped, and the symptoms of compression increased from that time, and which, though perhaps retarded by the means employed, gradually extended itself over the whole of the right hemisphere, producing frequent convulsions, strabismus, palsy of the left arm, coma, stertorous breathing, involuntary discharge of fæces, and death.

2dly, To the opinion which should be given at the coroner's inquest.

Here two questions occur, first, what was the cause of death? This can be easily answered; as, I presume, most persons would agree that death was in this case produced by paralysis of the respiratory muscles, caused chiefly, if not entirely, by the blood extravasated on the brain.

Secondly, to what was the rupture of the bloodvessel owing? This, to my mind, is not so satisfactorily answered, as there were three causes capable, either separately or combinedly, of producing it in a brain already diseased, namely, the blow, the fall, and the vomiting, with which for three days he was incessantly troubled.

ANALYSES & NOTICES OF BOOKS.

" L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

On the Influence of Physical Agents on Life. By W. F. EDWARDS, M.D. F.R.S. &c. Translated from the French, by DR. HODGKIN and DR. FISHER. With an Appendix and large Additions. Highley.

NOTHING surprises us more than that the able work of Dr. Edwards should have so long remained untranslated; that mere nationality, if no better motive prompted, should not have put in a claim for the honour of having such a work in our language—the native language of the author. That Dr. Edwards himself did not publish it in English, may be very well attributed to the homage which it may be supposed he felt himself bound to pay that nation which so liberally encouraged and rewarded his scientific labours: but he has afforded, we perceive, his sanction and assistance to the present translators, and has supplied them with some additional matter.

The history of the original work is, perhaps, not generally known: it was composed in various successive papers, which were presented to the Academy of Sciences, as subjects for the prize founded for the promotion of experimental physiology, and many of them were crowned with the highest honours. The papers were thus given to the public in several volumes of the *Annales de Physique et de Chimie*, between the years 1817 and 1823, and eventually appeared, in a collected form, in the year 1824. How highly the work has been appreciated by physiologists, since its valuable contents have been diffused among them, we need scarcely say: suffice it that it has thrown light on many of the most obscure inquiries, and has imparted a new impulse to many of the most difficult and retarded pursuits of the student of the animal economy. To those who are entering on such pursuits, and, indeed, to the general inquirer into the economy of nature, we cannot point out a surer source of satisfaction than they will enjoy in the perusal of this volume. The subjects which it embraces are of a wide range, and of the most interesting description. The effects of physical agents operating on almost the whole of animated nature are beautifully made out, and stated with the modesty and clearness which characterize the productions of the true philosopher. In the first part, we have an account of the influence of those agents on the batrachian tribe; in the second, their effects on reptiles and fishes; in the third, on warm-blooded animals; and the fourth part is

devoted to the consideration of the phenomena attending man and the vertebral animals when exposed to those influences. We wish our limits would allow us to give some ample extracts which we marked out; but the following, which is of practical application, and relating to a matter of vital interest, is all that we have room for.

"Very important considerations result from the difference of constitution at different periods of life. If the attentions which children require in climates and seasons little favourable to the preservation of their existence were generally understood and put in practice, it would considerably reduce one of the most powerful sources of mortality affecting that age in our climate. It is not confined to children whom the misery of their parents cannot guard from the rigor of the weather, but it operates to a great extent, without being either perceived or suspected, in families enjoying affluence, and in which it is believed that the necessary precautions are taken; because, cold being relative, it is difficult from our own feelings to judge of its effects on others, and because it does not always manifest itself by determinate and uniform sensations. They do not feel the cold, but they have an uneasiness or an indisposition which arises from it; their constitution becomes deteriorated by passing through the alternations of health and disease, and they sink under the action of an unknown cause. It is the more likely to be unknown, because the injurious effects of cold do not always manifest themselves during or immediately after its application. The changes are at first insensible; they increase by the repetition of the impression, or by its long duration; and the constitution is altered without the effect being suspected.

"There is a general precaution which would tend to prevent these effects, and which it is sufficient here merely to point out. It is to watch the changes which may come on during health at the decline of the year, and in the course of the cold season; and, however little it may be liable to derangement, to preserve heat by warmer clothing. If the clothing is adapted to the wants of the individual, it will contribute powerfully to guard him from the alterations dependent on the influence of the season: he will enjoy at the same time the advantage of being exposed to the open air in conditions of the atmosphere which would not injure his health.

"In countries where the cold is excessive, the feelings so strongly impress upon the inhabitants the necessity of guarding their children against it, that the particular care which they take renders this cause of mortality, perhaps, less in them than it is in temperate countries. It is sufficient, then, to feel this necessity, in order to find suitable means to meet it. These means are referable to several heads:—1. The modifications of the air, to adapt it to the system. 2. The preservation of the natural heat by clothing. 3. The changes to be produced in the constitution of the individual, in order to increase his power of developing heat, so as to extend the limits of the atmospheric variations to which he may be exposed without danger.

"People are frequently dissuaded from the use of warm clothing, and the external application of heat under the form of baths, by the idea that they may induce delicacy and greater sensibility to cold. This opinion is undoubtedly founded upon very general experience, and I think that the observations I have made on this subject do not weaken it: but other facts, equally well attested, tend to circumscribe it within just limits, and shew us that when the system does not develop sufficient heat, the means which we have just pointed out contribute to increase the power of producing it.

"Although the want of it is actually felt, the use of warm clothing is often declined, from the wish to reserve it for an advanced age: but it frequently happens that this precaution is the cause of preventing that age from being attained. The employment of the warm-bath is dreaded because water enervates; but this effect is obviated by reducing the duration of the bath, and thus making the application of heat predominate."

On turning to the original, we observe that the preceding passages are considerably condensed in the translation; and the same liberty is confessedly taken all through the work: but, to do Dr. Hodgkin justice, the substance is scrupulously preserved. We cannot but regret, however, that the tables are omitted, for they are the proofs—the data—upon which the reasoning is founded, and might very well have been printed in a compact form, for the benefit of the English student: the volume is

fully dear enough, without obliging him to purchase the French copy also. But to make amends, there is an ample Appendix, containing a number of valuable papers by Dr. Edwards, Dr. Hodgkin, Mr. Luke Howard, and others: there are also some interesting notes. On the whole, we are delighted to see the book in the mother tongue, and, it gives us much pleasure to be able to add, in a shape which we can strongly recommend.

A Brief Outline of the History and Progress of Cholera at Hull; with some Remarks on the Pathology and Treatment of the Disease. By James Alderson, M.D. &c.

We notice this brochure chiefly on account of two very well-executed engravings, representing the state of the stomach and bowels in cholera. The dark and congested state of the inner surface of the stomach, the head of the colon and ileum, are well delineated. The enlarged glands in the transverse arch of the colon are also shewn. No attempt is made at a systematic description of the disease, and there is no pretension displayed with regard to treatment. The work is what it professes to be—"a brief outline," and on this subject those are now the only readable productions.

The Madness and Folly of Religion: a Sermon delivered to Medical Students, at Maze Pond, Borough, on Sunday Morning, Nov. 11, 1832. By the Rev. T. Binney, of the Weigh-House*.

Our readers—the most fastidious of them, need not be afraid; we are not going to preach—it is not our vocation, nor would we lightly wield our pen on sacred subjects. A friend sent us the brochure, whose title heads this article, asking us to read it: we have done so, and now would persuade others to follow our example. The story runs thus:—In October 1830, the late Mr. Mann, then clergyman of Maze-Pond Chapel, was urged to address his discourse particularly to the young men of our profession, then just arrived in town to commence their studies; and as it was discreetly done, the pupils had the good sense and good feeling to receive it well, and the same reverend gentleman next year also adapted a sermon particularly to his juvenile hearers. But Mr. Mann having died, the annual address was this season postponed, and would have been altogether intermitted had not the author of the sermon before us undertaken the task. That we think the object a good one is clear from the nature of our allusion to it: that, in our estimation, Mr. Binney has done it well, must likewise be apparent; there is no overstraining to product effect—nothing to which the student of truth, be he old or young, can with reason refuse his assent, or which he can deny to be of paramount importance.

* Pulpit, Nov. 15, 1832.

An Historical Dissertation concerning John Bull's Medical Panics, Ancient and Modern, &c. &c. By Adam Dods, M.D.

The title of this work led us to take it up, in the expectation of finding something either in the way of instruction or amusement for our readers and ourselves. We have found neither. It is a collection of the most stupid rhapsodies that ever were penned—often incoherent—never to the point. How came any man with M.D. after his name to write such trash? Take a specimen; it is all in the same style.

"*Peace proclaimed* to all the world, not between Belgium and Holland, but between the faculty, particularly the Board of Health, and Dr. Dods. While I was sitting very quietly in the office, correcting the press for the printer's devil, Mr. Pierpoint and Dr. Streeten were winding their way up stairs, calling out for Dr. Dods, the former with a stentorophonic and thundering voice, and the latter with one more soft, like an echo of the other, and both out of breath for some purpose, and very busy about nothing. At this critical moment a pigeon flew past the window, flapping its wings in the rays of the sun, as mighty coming events are said to cast their shadows before. I doubted whether their object was to take me by main physical force to the cholera hospital, where I should be placed in a most delightful marshy situation, to inhale the pure foggy atmosphere, surrounded on all sides with ponds and ditches full of decomposed vegetable and animal mat-

ters, and stagnated water, emitting effluvia, "like crush'd perfumes exhaling to the skies." Agues, remittent fevers, typhus, bilious fevers, and putrid sore throats, were instantly floating in my brain. However, I happily thought of Mr. Addison's plan of warming the atmosphere and dispelling "terrestrial radiations" by large fires by night, and firing cannon and wasting gunpowder by day, on the top of Malvern Hills. Then the parishes of Ledbury would send Mr. Sewell to visit me in *my* cholera hospital, as they, it is said, paid him five pounds to go to Gloucester to gain further information and instructions respecting the nature and treatment of the disease. Being recovered from my fright, I was able to attend to the wishes of the two gentlemen, which were to request me to attend the Board of Health at the Guildhall, which I did. After some rational, moralizing converse, and explanation about the devil, it was soon discovered by the meeting that I had been thinking more about the printer's devil than his Satanic majesty, consequently peace, harmony, sociality, and good-will to all mankind, were recorded by Dr. Streeten, honorary secretary, and proclaimed aloud by his worshipful the mayor, H. Clifton, Esq. Think o' that."

It may possibly be asked what our motive is for noticing such a production. It is this: the author purposes "in a very short period to again resume and continue the subjects as specified in the title-page, and complete them as speedily as my professional engagements and the printing will permit—*provided the public will subscribe for a second number.*" We have thought it right to let "the public" know what they would be subscribing to, and so take our leave of Dr. Dods.

MEDICAL GAZETTE.

Saturday, November 24, 1832.

"Licet omnibus, licet etiam mihi, dignitaten *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

QUERY—DO VEGETABLES PRODUCE CHOLERA?

The market-gardeners of London, finding their trade and "occupation gone," by the supposed choleric tendency of vegetable diet, applied, in September last, through Mr. Mandano, a respectable member of their body, to several "*eminent*" medical men, to dispel the delusion which they believed the medical profession to have either created or fostered. The replies of the "Doctors" are contained in a pamphlet* which lies before us, and a more amusing collection of letters we have not met with for a long time. We must treat our readers with some of the choicest morsels in this literary olio.

The letters are thirty in number, and from men, some of whom are very well known, while as to others, the present may be looked upon as their first appearance "on any stage;" and right anxious they are to appear to the best advantage.

Several of the writers are unwilling to admit that the prejudice in the public mind against vegetable diet, was in any degree traceable to the medical world. We suspect, however, that in spite of these disclaimers, the market-gardeners are right,—we well remember how industriously some of those little men who are "out in all weathers," laboured to prove the identity of the epidemic cholera with the autumnal cholera of Sydenham, and how gladly they seized upon any thing as a *cause* of cholera, provided they could but escape from the doctrine of "personal communication." Sir Henry Halford, in his reply to the gardeners, acknowledges "that the cholera morbus of *this* country is sometimes produced by an *abuse* of fruit and vegetables, particularly if the former be unripe, or the latter ill boiled."

But what say the authorities? In Dr. Bisset Hawkins's History of the Epidemic Cholera of Russia, we read (in page 4) the following precautionary instructions issued by the Russian go-

* Opinions of several eminent Medical Men with regard to Vegetable Diet, in reference to Cholera. London, 1832. N. Archer, pp. 32.

vernment on the approach of the epidemic cholera. It is rigorously prohibited to eat apples, plums, melons, water-melons, cucumbers, raw turnips, carrots, mushrooms, and *other vegetables of the same sort.* Again, in Dr. Webster's Essay on the Epidemic Cholera, at page 98, we find it thus written:—"When the disease at Riga had arrived at its greatest height and intensity, the medical practitioners, *as it has been likewise in this country*, generally observed, if very indigestible food was used by the inhabitants, then attacks of the cholera were more severe and extensive than otherwise, and it was hence remarked that cucumbers, *and many other kinds of vegetables*, especially if used either raw or improperly cooked, were a *most prolific* exciting cause of the disease."

In one of the early circulars of the Central Board, the public are cautioned to eat "sparingly" of fruit and vegetables; and in that of December 13, 1831, "*all raw vegetables*" are interdicted, as being "acescent and unwholesome food." The instructions of the first Board of Health on this subject are thus alluded to in Dr. Birkbeck's letter to the market-gardeners. We have not been able to verify the assumption of the learned writer as to the spuriousness of the document, which, therefore, our readers must take on his authority:—there is something quite characteristic in his mode of dealing with the question.

"The absurd, and, I am sorry to find, most mischievous rumour of which you speak, has not, I hope, for the credit of the profession, 'emanated,' as you assert, 'from the medical world.' It is true, indeed, that in a very strange document, uttered by a body ridiculously entitled a Board of Health, to which the name of the President of the College of Physicians was (surreptitiously of course) appended, something was advanced against the use of fruit and vegetables in reference to cholera; yet, so far as I have been able to discover, no opinion of the kind has been maintained by any individual who, medically speaking, ought to be considered either intelligent or respectable."

The reply of Dr. James Johnson to the market-gardeners, touches on the same point; and is, moreover, in other respects so curious, that we give it entire."

"I have no hesitation in saying, that, in the course of my investigation into the nature and causes of the recent (and I hope it will soon be said, *late*) epidemic, few or no cases presented themselves to my observation where a temperate use of wholesome fruit and vegetables had any thing to do with the production of cholera. The cause of the disease appears to me to have been an inexplicable *something* extricated from the earth, or floating in the air, beyond the control as well as the knowledge of man; that this cause, whatever may be its nature, was often called forth into activity by *excesses* of all kinds, and by the *abuse* of unripe fruit and unwholesome or badly-dressed vegetable, I have no doubt; but the same might be said of almost every species of food and drink.

"The panic, therefore, respecting the use of fruit and vegetables in moderation, was wholly without foundation, in fact, and is rapidly subsiding. I have never made any alteration in my own diet or that of my family, during the prevalence of the epidemic, beyond that of temperance in quantity, and attention to the quality of fruit and vegetables in the height of summer and beginning of autumn, when the above articles of diet are abundant, and the season of the year predisposes to bowel complaints. I have no doubt, therefore, that with the disappearance of the grand and primary cause of the epidemic, the absurd prejudice against the temperate use of fruit and vegetables will also vanish from the mind of the public."

From this letter, we learn that the cause of cholera is "inexplicable and beyond the knowledge of man;"—yet in the very same sentence we learn two things concerning it: first, that it is either extricated from the earth or that it floats in the air; and, secondly, that it is often called forth into activity by excesses. How Dr. Johnson attained even this limited information regarding that

which is "beyond the knowledge of man," or why he thus discourages all farther investigations into the cause of the disease, as vain and profitless, are points on which we confess our entire ignorance. One other circumstance struck us in perusing this letter. The only alteration, he says, which he made in his household during the prevalence of cholera, was to pay attention, "in summer and autumn," to the quality of the vegetables and fruit which were consumed in his family. Are we to understand from this, that, in winter and spring, the worthy Doctor is himself, or suffers his patients to be, *inattentive* to the quality of the potatoes and apples which they consume?

The letter of Mr. Gossett is curious, as shewing the ingenuity with which a man can sometimes argue on both sides of a question, without saying any thing upon either that can be brought against him as his opinion. It runs thus:—

"Having been called upon by you, acting, I presume, for the market-gardeners as a body, to state my opinion respecting the wholesomeness of vegetable diet, I should consider myself culpably indifferent to the interest of a very numerous and respectable class of individuals were I not to take the earliest opportunity of acquainting you with the result of my experience on the subject: in doing so, however, some degree of caution is requisite, to guard against any misconstruction of my opinions, and to prevent the possibility of this public avowal being considered as opposed to the instructions I often find it necessary to give to my patients in private. Of course most of those who apply to me for advice are persons suffering from some form of disease not unfrequently resulting from a disordered state of the stomach or bowels, when I usually enjoin the strictest abstinence from vegetable food; yet it would be manifestly absurd to infer, because the discontinuance of the use of vegetables may be necessary to the removal of disease, that it is also conducive to the maintenance of existing health. With this reservation, I have no hesitation in stating my belief that the moderate employment of cooked vegetables is useful in preserving the due action of the bowels, and thereby preserving the health of the system in general."

After these, and a hundred similar denunciations, against the *abuse* of fruit and vegetables, we can hardly wonder at the public foregoing the use of vegetables altogether, as the surest means of avoiding the risk of any abuse of them. The most eminent practitioners, however, are all agreed in condemning this extreme; indeed it is really curious to observe their unanimity on this point.

The following sample of the opinions of London doctors on vegetable diet, as the cause of epidemic cholera, will, we trust, be sufficient; and to them we invite the especial attention of those gentlemen who see, in the late epidemic, nothing more than an aggravated form of the autumnal cholera of this country.

Sir Matthew Tierney thinks, "the progress of the present epidemic has been quite unconnected with the proper use of fruit and vegetables."

Dr. M. Hall says, "I have not met with a single case in which I suspected that vegetables had induced cholera."

Dr. Elliotson tells, that "If providence has ordained a supply of certain food at a certain time of the year, we may feel assured that such food is good for us at that time of the year; if fruit or vegetables are of bad quality, or eaten in excess, its effects will arise, and cholera, no less than many other diseases, may be disposed to. I have never been able to trace an instance of cholera to fruit or vegetables, and yet have seen a great deal of the disease: it has been excess in drinks to which I have satisfactorily traced cholera in most cases. I myself, though continually with cholera patients, have eaten fruit and vegetables all the season in great abundance, and so have all my family, with no ill effect*."

Dr. Frampton remarks, "I have had no reason whatever to suppose that any such cause has in any degree contributed to excite or produce the disease."

* In the original the whole of the above is given as one unbroken sentence; but as this appears to have been a mistake of the printer, we have altered the punctuation.—E.G.

Dr. Conquest will "have much pleasure in doing all that an individual can do towards removing a prejudice which has nothing for its support but ignorance and fear."

Dr. W. Philip expresses himself thus: "When I have been obliged to visit professionally those labouring under the disease, the diminution of the vegetable part of my diet has never been among the precautions I employed."

Dr. A. T. Thomson, in regard to vegetable food, thinks it an "absurd idea that it produces the attacks of Asiatic cholera."

Dr. Clark's statement is—"I have seen no proof that a moderate use of well-cooked vegetables had any share in producing cholera."

Dr. Wilson declares, "So far from discouraging the use of well-dressed vegetables as articles of food during the prevalence of cholera, I am generally urging those who consult me to admit them as leading principles in their diet."

Lastly, Sir Henry Halford writes thus: "I do not believe the disease which has prevailed lately in this kingdom, called Asiatic cholera, to have any connexion whatever with a common use of the fruits of the season."

If the doctors did originally encourage the prejudice under which the market-gardeners have suffered so seriously, they have assuredly now done their best to wipe off the reproach.

MAGISTRATES CANNOT COMPEL MEDICAL MEN TO CERTIFY WITHOUT A FEE.

A FEMALE was wounded by a stone thrown at another person; she was taken to the hospital. The Mayor desired the surgeon in attendance to send him a certificate of his patient's condition. He declined to do so, unless he was paid for his trouble. His worship was angry, and wrote to the Government on the subject. The following is the answer to his application:—

Dublin Castle, Nov. 13, 1832.

SIR,

I have received your letter of the 7th inst. with respect to a refusal on the part of the Hospital Surgeon at Limerick to give, without a fee, a certificate of the state of a girl, named Mary Noonan, who had been seriously injured by a stone, thrown by Jeremiah Ahern at another person; and having by the Lord Lieutenant's desire referred your communication to the law officers of the Crown, I am to acquaint you, for the information of the Magistrates at Petty Sessions, that he is not aware of any law which obliges the surgeon of an infirmary to give an opinion in cases of this nature.

I have the honour to be, &c.

E. J. STANLEY.

ACADEMY OF MEDICINE, PARIS.

November 13, 1832.

Presentation of Clot-Bey and his twelve Egyptian Pupils.

THIS was a striking scene. At an early hour, two of the most commodious benches were occupied by the Egyptians who have come to study medicine in Paris, and in the midst of them, distinguished by the brilliant magnificence of his costume, sat Dr. Clot, physician general to the army of the Pacha of Egypt, director and founder of the school of Abouzabel. All eyes were turned on this interesting groupe. The young foreigners have dark, strongly-marked features, and wear no beards. They have a distinction of rank among them—a chief, with his assistants and sub-assistants: these were clad in a scarlet vest and pantaloons, richly embroidered with gold; on their heads a red cap, in the Grecian fashion. The remainder of the pupils wore a simple blue dress, and cap of the same colour. M. Clot, in addition to the richly embroidered scarlet costume, wore a splendid Cachmere for a turban, and a superb damask for a girdle: on his breast were diamond stars. He looked perfectly oriental: one should know beforehand that he was a native of France, otherwise it would be difficult not to suppose him an Egyptian.

The Academy was in the highest degree anxious to hear from M. Clot an account of his proceedings in Egypt, and the President, as interpreter of the general wish, invited the visitor to gratify it. M. Clot accordingly approached the bureau, and began his story in the midst of profound silence. After a few words of apology for his want of habit in addressing an audience in the French language, he thus proceeded:—

"I lived at Marseilles, a practitioner of some years standing, when I was applied to by an agent of the viceroy of Egypt. I was invited to undertake the organization of the service of health in that country. I consented, and, with a few attendants, embarked in January

1825. I was charged at first with the military service. The troops of the pacha, at that time in Lower Egypt, amounted to about 25,000 men; the remainder of the army was in the Morea. The officers of health were all of the lowest and meanest description — persons who had risen, from being hospital attendants, to the rank of practitioners-in-chief—and all without any examination into their abilities. The pacha entreated me to organize the service after the French mode.

I found, in the first place, a supreme board of health, consisting of the first physician of his highness, his physician in ordinary, and a practitioner of the Court. I did not join this board: I was appointed physician-general to the army. I then set my plans to work; the first of which was to examine every officer of health, and to reject those who should prove insufficient. Of course this made me many an enemy; for many an ignorant person was dismissed: I narrowly escaped death from the hand of an assassin who struck me in the amphitheatre.

My officers of health were honoured with military insignia, which contributed at first very much to increase the jealousy conceived against them; but that also passed away.

The Pacha's army now amounted to 60,000 men, and there was a grievous want of medical officers. To remedy this want, I proposed to convert the hospital of Abouzabel, which is near Heliopolis, and within about four leagues of Cairo, into a medical school. I collected a hundred young Arabs for my first pupils.

But now began my real difficulties. How was I to teach these young people, with whose language I was unacquainted?

I happened to find at Cairo three individuals who understood French, Italian, and Arabic; but they knew nothing of medicine. I said to them, "Come, you shall be physicians; but first you must be scholars." I gave them a lecture, and said, "Now you have had your first lecture; study it, and write it for me in Arabic." To assure myself of the correctness of the translation, I had it re-translated into French. It was then dictated to the young Arabs, who wrote it down, and were examined through the interpreters. In this way I got through a course of anatomy.

Our theoretical mode of instruction soon began to fail us; we found that we should proceed practically to work with the *dead body*. This, however, looked like an insurmountable difficulty. The viceroy would not undertake the responsibility of permitting it: the minister of war was equally unwilling to give his sanction. One method alone remained for me, and that I resolved to try. I visited the Ulemas, the Mohammedan priests. These functionaries were long sensible of the decline of their influence, and saw that it could only be recovered through the study of medicine—the people having such a veneration for the Francs, all of whom they conceive to be physicians, and whom they generally accost by tendering them their pulse to feel. The chief of the Ulemas, a superior man, did not refuse to reason with me on the matter. His principal objections were these:—How was it possible to remove the idea of profanation which the Egyptians attached to the violation of the dead? And how could we satisfy the theological notion that the dead are sensible of the tortures inflicted upon their inanimate remains? I readily disposed of the latter objection. "Suppose," said I, "that the dead *do* really feel the torture of dissection, how are they better off if they wait to be gnawed by the worms? their pains can only be anticipated by a few hours; and should those pains be any objection, when the health and well-being of thousands of the living are depending upon them?" And as to the general utility of anatomy, I asked, "How would you best make yourself acquainted with the mechanism of a watch? should you not take it to pieces and examine every part in detail?" "Well, well," replied the chief priest, "go on, dissect; but mind I do not give you leave; I will only say nothing; I will not hinder my children from dissecting." It now only remained to overcome the repugnance of the pupils, and to secure myself from the dangers of popular prejudice. The pupils I gradually habituated to the contact of the dead body; and before three months they were all warm advocates of dissection. Through them also I obviated the risk that might arise from popular abhorrence. The pupils persuaded their parents and friends, and *they* the rest of the people; after which every thing went on smoothly. I even invited the Ulemas to witness our proceedings. The chief Ulema attended; and even Ibrahim Pacha himself, with some of the officers of his court, assisted at an entire lecture on anatomy. (*General murmur of approbation through the Academy.*)

Five years thus rolled on, consecrated to the business of instruction. The land forces were now supplied with medical officers, but the navy was still deficient; the expedition into Syria also required a supply. There was thus a rapid demand for my pupils; and when the cholera came they were all put in requisition. The cholera, as it ravaged Cairo, was a far more dreadful scourge than was ever known there before. In 29 days it cut off 60,000, out of a population of 260,000. The utmost that the plague ever cut off

was 40,000 in the course of six months. All my pupils, as I said, were employed during the epidemic. One of them, now present, was attached to the household of the Pacha, and treated sixty cases with success. I lost, however, twenty or thirty of my pupils (out of 150) during the ravage of the cholera. Abouzabel, which contains about 1800 inhabitants, lost one-half its population.

It was after the visitation of this pestilence, when the pupils reassembled, that I sent out a hundred of them to join the expedition in Syria.

I attribute the wonderful progress made in the school of Abouzabel to the method of mutual instruction which we adopted there, and mainly to the excellent capacity of the Arabs, who are very intelligent, smart, and possessed of great powers of retention.

But to conclude. It was in consequence of observing the little stability of strangers in Egypt, and of being persuaded of the paramount advantages of native teachers, that I proposed to the Pacha, to whose inexhaustible benevolence I was so much indebted, to send into Europe a certain number of young men to be instructed in the schools of medicine, and who should bring back with them a store of professional information. Mehemet Ali readily acceded to my request. He chose France; and commissioned me to select twelve of my pupils, whom I should conduct to my country. I only regretted that I could not take them all.

With regard to myself, I have been requested by the Pacha to wear in France the oriental costume, that my countrymen might see that I was raised to the rank of Bey. I have sacrificed nothing for this dignity; I have waived no opinion; I have compromised no duty of conscience. The toleration of my kind patron is without bounds; and, however true it may be that certain Frenchmen have attained the dignity of pacha, by changing their religion and becoming Turks, *I* have made no such sacrifice: it was not even demanded that I should. I am both a Bey and a Christian! I accepted, with pleasure and gratitude, a title which I did not solicit, and one, I may add, which is worth much to me in a pecuniary point of view. My appointments, which were originally fixed at 8000 francs, were afterwards raised to 12,000; but, by the addition of the title, I am the possessor of 36,000 francs per annum. Nor is the title of Bey all: the Pacha insisted also upon giving me the rank of a colonel. He wished, he said, that I should be distinguished from my professional brethren by the decoration of a star; and in bestowing it on me, he tapped me familiarly on the shoulder, and said with a smile, 'This will make you less a Christian.'"

M. Clot's interesting recital was followed by the most marked applause from all parts of the Academy.

FATAL QUACKERY.

An inquest has been held at the Black Horse, High-Street, Marylebone, for two successive days (17th and 19th.) before Mr. Stirling, the coroner, on the body of Mary Eliz. Landon, a child of five years, who is said to have come by her death through the improper treatment of Mrs. Catherine Spiller, a *doctress*, residing at Highgate. The child was put under her care to be cured of *tinea capitis:* the doctress applied plaisters of a powerful description, and the child's death ensued. On the first day of the inquest, evidence touching the general facts was given; but an adjournment took place, that the body should be professionally examined. We subjoin the chief proceedings of the adjourned inquest.

Mrs. Spiller, accompanied by several persons of very respectable appearance, came in coaches at an early hour, and were accommodated with a private room. Mrs. Spiller was fashionably dressed.

Mr. Carter, surgeon, residing at No. 2, South-Street, Manchester-Square, deposed as follows:—In consequence of the wish expressed by the jury last Saturday, I, assisted by Mr. Vickers and another medical gentleman, have made a careful examination of the deceased child's body. We removed the plaister from the child's head, and washed it thoroughly with soap and water, in order that we might have a clear view of the state of the surface. I had seen the child's head a week or ten days before, and the appearance of it yesterday morning was as different from what it was then as circumstances and that lapse of time could possibly have produced. It appeared that some powerful corrosive "remedy" had been applied, and there was a considerable sloughing almost all over the head. On the left side there was an extensive slough, in some parts penetrating into the skull. About two inches above this was a still larger slough, one inch and a half in length, and one inch wide, penetrating through the integuments completely to the bone. At the back of the parietal bones of the head was another extensive slough, one inch and a half in length, and three-quarters of an inch in breadth. There was another slough about the size of a sixpence on the left side of the hinder part of the head. We then proceeded to examine the internal parts, first the brain, which we found in a particularly healthy and fine state, not exhibiting the least marks of disease whatever. We then opened the abdomen and chest, and the whole of the internal parts ap-

peared to be in a perfect state of health, nor could we discover the slightest traces of any latent disease, or any organic morbid affection whatever, to account for the child's death. It certainly could not have been caused by any internal affection. I conclude from the whole of the examination that the death of the deceased could have been caused by nothing but the outward appearances on the head, which were certainly amply sufficient to destroy life.

The Coroner.—It appears that Mrs. Spiller told the child's father to come again on the Saturday, and he did not come until Sunday, when she said it was of no consequence; do you think, sir, that the plaister remaining on an additional twenty-four hours might have caused the mischief?

Mr. Carter.—It is certainly possible.

The Coroner.—Would not the injury be increased in extent by suffering the plaister, supposing it to contain corrosive matter, to remain on an additional twenty-four hours after the skin had been destroyed?

Mr. Carter.—The longer that any corrosive matter remains on the human body, the greater the mischief likely to be caused, certainly; but in such a case as this, where the head is the seat of the injury, the moment the integuments were destroyed and the bone penetrated, death was inevitable, though not immediate, and the original injury might have been done in a very few hours after the plaister was first applied. I had no opportunity of seeing the first plaister, to ascertain of what it was composed.

By the Jury.—It is probable, and most likely, that the injury which has produced death was caused during the first three days, and that the plaister remaining on for an extra twenty-four hours had very little to do with it.

Mr. William Randall Vickers, of Thayer-Street, Manchester-Square, surgeon, was called, and his evidence was corroborative of that given by Mr. Carter, with one or two additions. He stated, that on removing the scalp, the inner surface was highly inflamed and partly ulcerated. On the back part, the bone in some parts was almost bare, and the dura mater firmly adhered to the inner surface of the skull, and it was difficult to separate it. There could be no doubt that the death of the child was caused by the application of some highly-irritating ingredient to the external surface of the head. The child was generally healthy, with the exception of some slight herpetic eruptions on the groins, elbows, and the calf of the legs.

Mrs. Spiller was then brought in, and asked if she wished to say any thing? She said she was desirous of making the fullest statement she could. The coroner cautioned her that whatever she said would be taken down, and might be made evidence against her; but she persisted in making a statement, the substance of which was, that she had cured a great many persons, young and old; that she had administered the same remedies to the deceased that she had to other patients successfully; and that Mr. Lanton, the father, said at the last visit with the child, that he was perfectly satisfied and much pleased with the treatment.

This part of Mrs. Spiller's statement was positively denied by Mr. Landon.

The Coroner, in a short charge to the jury, observed that it could not be supposed that Mrs. Spiller had any positive design to do mischief to the child; but if persons who were ignorant of the nature and properties of drugs, or other nostrums, chose to take upon themselves to administer them, and the life of any one of his Majesty's subjects was thereby endangered, they must take the consequences awarded by the law. Mrs. Spiller had said that she had cured several persons; that might or might not be, but it would make no difference in the present inquiry. That which might be of service to one, might be fatal to another.

The room was then cleared of strangers, and the jury, after deliberating for a short time, returned a verdict of "Manslaughter against Catherine Spiller." Mrs. Spiller was immediately conveyed to Newgate upon the Coroner's warrant; and the witnesses were bound over to prosecute.

ST. GEORGE'S HOSPITAL.

On Thursday last, November 22, Mr. Brodie amputated the upper extremity at the shoulder-joint, for disease of the bone and adjacent parts. The operation, at all times rather a formidable one, received much painful interest from the violent struggles of the patient; by which the steps of the proceeding were retarded, and the prevention of hæmorrhage rendered exceedingly difficult. After the posterior portion had been divided, the trapezius, having no longer any antagonist, tilted up the scapula and end of the clavicle, so as to remove the point where pressure was applied farther from the artery; and great force was required to overcome this evil. It was intended to have removed the scapula also; but as some blood was lost, and as the patient was so extremely unmanageable, it was deemed better merely to leave a free opening, communicating with the diseased portions of bone. The patient to-day (Friday) appears better than could have been expected. We shall give the details of the case when it is completed.

PRESERVATION OF BODIES.

An important discovery has recently been made in France, by MM. Capron and Boniface, chemists, of Chaillot. By a process to which they have given the name of *Momification*, they have succeeded, after numerous experiments, in so modifying the known processes of preserving bodies as to reduce them to mummies, leaving all the forms unaltered: even the features remain so perfectly unchanged, that correct portraits may be taken at any length of time after death; and as the body is not enveloped in bandages, as in the Egyptian method, the natural forms are kept entire. The operation requires but a few days, when bodies become inaccessible to worms; they may also be exposed to all the variations of the atmosphere without undergoing any change. At a late meeting of the Academie des Sciences, a human body, and also two hearts, preserved in this manner, were exhibited, and the process appeared complete: although these preparations had been made several weeks, not the slightest alteration had taken place, and even the discoloured state of the skin occasioned by the scar of an old wound was fully perceptible.

LECTURES
ON
CASES OF DISEASE,

Treated in the Dispensary of the University of London.

By Anthony Todd Thomson, M.D.

Introductory Remarks—Psoriasis Gyrata.

Gentlemen,—The occasion which has brought us together imposes upon me the pleasing task of explaining to you, at certain intervals, the nature of the diseases of those persons who present themselves for advice and medicines at this institution. The object of your attendance is to see disease in its various forms; to observe, and learn to distinguish symptoms; to trace them to their causes; and to mark the influence of medicines—in a few words, to acquire how to apply and reduce to practice the instructions which you have received from attending lectures, in order that you may be fitted for the end and aim of all your studies—the actual practice of your profession. I shall not pause here to notice the advantages which Dispensaries afford to the attentive student, for obtaining the knowledge to which I have alluded; the opinions which I hold upon this subject, and which I delivered to my young friends in my introductory discourse from this chair last session, are before the public, and I have heard nothing urged against them which induces me to doubt their accuracy. Hospitals and Dispensaries possess each their advantages; and if those, whose duty it is to teach the nature and treatment of diseases in either, honestly perform their tasks, the opportunities afforded of studying diseases in both will be found of the greatest value to the student who is earnestly desirous of acquiring practical information. If the nature of Dispensaries does not afford to him the means of tracing the influence of remedies administered under circumstances the most favourable for their operation — namely, under the eye and the control of the physician, it introduces him to that kind of practice which is afterwards to constitute the real business of his life. He witnesses in them all the difficulties which are encountered in private practice; the interests, the passions, the appetites, and the prejudices of patients, working against him; he sees these, and he learns how to combat them. I should say, that the attendance on an Hospital cannot supply the information which may be frequently obtained at a Dispensary, any more than that at a Dispensary can compensate for the want of that which an hospital affords. A certain period spent at both is requisite to give the finish to a complete medical education.

Such being the case—assuming that you are aware of the importance of your attendance in this place—it is scarcely necessary for me to urge the necessity of your undivided attention during the examination of every patient who presents himself; for although you will find many cases so closely resembling each other as to leave no doubt on your mind that they may be justly regarded as constituting one form of disease, yet, if you observe closely, you will also discover, that each case presents some peculiar feature, which demands a modification of the general treatment applicable to the class to which it belongs. The tact in discovering such deviations constitutes much of the skill which leads to successful practice; but it is that part of your professional knowledge which is the least capable of being conveyed by instructions; it must be the result of close observation. Nature must be questioned, and truth investigated, in such a manner as shall leave the imagination

unemployed; nothing must be taken for granted. But, although no teacher can convey to you the mode of acquiring this information in each particular case, yet the general method of inquiry may be attained; and it is on this account that I urge your undivided attention during the examination of the patients. Lay a solid foundation, by accumulating observations, and, by rising from these, strive next to reach the causes of disease. In attending to this, you ought also to endeavour to make out in your mind the reasons for the line of practice which is adopted; and if you cannot satisfy yourselves, demand an explanation. I am induced to recommend to you this plan of proceeding, because it is impossible for the physician of any institution, so much resorted to by the sick poor as this is, to pause and comment upon each case that presents itself; and it is more useful for you, gentlemen, to exercise your judgment, than to lean solely upon the information which you can always elicit from your teacher. At this same time be assured, that no inquiry shall be considered too trivial not to merit an answer on my part. I shall endeavour either to guide your minds, so as to enable you to overcome the difficulty yourselves; or I shall enter into a full explanation of my views in prescribing, or candidly acknowledge my inability to satisfy your doubts. It is by such a communion and free intercourse of ideas amongst us that you will profit by your attendance here; and the expectation of seeing it realized emboldens me to prognosticate, that the retrospect of what you have acquired, even in this limited school of practice, will convince you, that it is the conscientious performance of his duty on the part of the teacher, and that earnest desire for information which alone insures attention on that of the pupil, which render instruction valuable, whatever may be the name of the place in which opportunities for imparting and receiving knowledge are afforded. Having said this much, let us now revert to the more immediate object of this discourse.

In the short period which has elapsed since the commencement of this session, among many other diseases, several cases of cutaneous eruptions have been admitted. Three of these are Psoriasis, and one of them has presented so peculiar an aspect that your attention has been particularly attracted to it. I refer to the case of Sarah Saxby, an Irishwoman, who is labouring under that form of Psoriasis which is termed *gyrata*. The following is the history of the case, as taken down from the examination of the patient on her admission, October 13, 1832.

Sarah Saxby, a native of Ireland, æt. 28, is a married woman, and the mother of several children. She has been the subject of a cutaneous eruption ever since she left Ireland, which was four years ago. It first appeared on the face, but, after some time, extended to the neck and occiput, where it is now situated. The eruption occupies the whole of the back of the neck and the right shoulder, forming various tortuous lines and circles, which, to an unexperienced person, appear like large earth-worms, writhing in various directions; the joints of which are strongly marked. She states, that the longest interval from the disease which she has enjoyed, since its commencement, has not exceeded a month; and also that she had a similar eruption on the legs when a young girl. She is frequently affected with headache and drowsiness, especially if the eruption suddenly disappear. The catamenia is regular, except when she is suckling. The bowels are habitually costive; the tongue is white; the pulse 90, quick and hard; the heat of body considerable, and there is much thirst.

She was ordered to be bled to twelve ounces, and to take nightly a dose of purgative pills, with the following mixture:

℞ Liquoris Potassæ, ℥iij.; Decocti Ulmi, ℨviij. M. sit mistura cujus sumantur Cochlearia iij. majora, ter in die.

15th.—The patient having caught cold, and being feverish, was ordered to discontinue her medicine, and to take the following:—

℞ Liquoris Ammoniæ Acetatis ℨij.; Vini Ipecacuanhæ, ℥jss.; Potassæ Nitratis, ℥j.; Misturæ Camphoræ, ℨvj. M. Sum. Cochl. iij. majora ita q. q. horâ. Perstet in usum pilularum purg.

17th.—All fever having abated, she returned to the use of her mixture containing the solution of potassa; which she has continued ever since. The eruption has greatly declined, and in some places is scarcely visible. A patch resembling Psoriasis *diffusa*, which was seated on the arm, has disappeared.

Now your attention having been particularly directed to this case, induces me to offer you a few remarks on the nature of Psoriasis in general; and, as the patient is in attendance, we have an opportunity of satisfying ourselves respecting the real character of this form of eruption.

Psoriasis is one of the order of scaly eruptions, so named from the scales, which are rather the consequence of the diseased state of the cuticle than the disease itself,

being so constantly present as to distinguish it from other eruptions. How far authors are correct in regarding Lepra, Psoriasis, and Pityriasis, as distinct genera of diseases, may admit of a question, but they are at present regarded as such; and our knowledge of cutaneous disease is not sufficiently advanced to enable us satisfactorily to decide. That these three genera, however, differ essentially from Ichthyosis, which is also classed as one of the squamæ, there can be no doubt: but, in my opinion, Ichthyosis has been inconsiderately arranged as a scaly eruption. In Psoriasis, as well as in the other scaly eruptions, the scales appear to proceed from an altered action of the vessels secreting the cuticle, which, in this case, are not merely separated, but are changed into small opaque, thickened, white laminæ, of an elongated shape, easily detached, and displaying the surface on which they lie to be red, inflamed, slightly elevated, and in truth actually papular.

In examining carefully the eruption, in the patient before us, [the patient was brought in] we will not hesitate, notwithstanding the tortuous and vermicular form of the eruption, to pronounce that it is a mere variety of the more common forms of the disease, Psoriasis *guttata* and *diffusa*. Emerging from amongst the roots of the hair, and passing down upon the neck behind the right ear, we observe that within the gyrations there are many small irregular dots and oval patches; and on a closer investigation of the serpentine lines of eruptions, there is much reason for thinking that these consist of such patches, placed end to end.

All the instances, which are only four, in which I have seen this form of the disease, have occurred in females, and the eruption has occupied the same part of the body as in this woman, namely, the back of the neck and the shoulders. In the declining state of the complaint, which has been a week under treatment, the raised appearance of the axis of each tortuous line, and its transverse cracks, are not so obvious as they were; but you have here a good opportunity of marking the manner in which the eruption disappears, a circumstance which, as I shall have many opportunities of proving to you, is one of the diagnostic symptoms which distinguish Psoriasis from Lepra. The patches have disappeared from the circumference, and the tortuous lines are not half their original breadth; they are marked on one side by a faint red line, and on the other by thinner, less elevated, and distinct scales, than you saw a week ago.

Some of the varieties of Psoriasis arise from local irritation; for example, those which appear on the hands and arms of bakers, Psoriasis *pistoria*, and of washerwomen, Psoriasis *lotorum*; but in general the causes of the disease are obscure. In the case before us there was an evident excited state of the system; the face was swelled, red, and heated, the eyes suffused, and the tongue furred; the pulse quick, full, and bounding, the bowels confined, and the urine high-coloured. The woman complained also of excruciating headache, want of sleep, and that bruised feeling of the limbs which invariably attends inflammatory fever. It might be questioned how far this condition of the system is connected with the eruption; but that it at least augments, and has renewed it, is true, as this occurred whilst the patient attended me at home, before she was admitted at the Dispensary*. In the majority of cases, not purely local, which I have seen, the digestive organs have been more or less in fault; there has been considerable irritability of stomach, and a predominant acidity. In children this state may be traced to crude and improper diet, which is sufficient to account for the disease; but in adults this state of the stomach, with which the skin evidently sympathizes, is often the consequence of mental anxiety, and whatever can lower the general powers of vitality. I have seen Psoriasis not an unfrequent attendant of the gouty diathesis, and occasionally the consequence of drinking cold fluids, while the surface was bathed in perspiration from severe and exhausting exertion.

It is not difficult to comprehend, when we reflect on the intimate connexion between the condition of the stomach and that of the skin, that an irritable state of the former may be accompanied by a corresponding irritable condition of the latter sufficient to induce such an inflammatory state of the cutaneous capillaries as should produce the inflammation and exfoliation of the cuticular scales; but it is extremely difficult to form any idea of the cause of the peculiar form of the eruption in this and similar cutaneous affections. Indeed the characteristic forms of eruptions in many instances; the horse-shoe form of that in Measles; the circular patches of Lepra; the progress of Scarlatina from the head and trunk to the extremities; and of Roscola in the opposite direction, afford food for reflection, and are facts worthy the investigation of those entering upon the practice of their profession, — when time and opportunity are favourable to such inquiries.

Women, in general, are said to be more

* Since this lecture was delivered a slight recurrence of the eruption has taken place, owing to a severe catarrh which attacked the patient, after exposure to cold and damp.

liable to Psoriasis than men, and those especially of a sanguineo-melancholic temperament, with a dry and languid circulation: but our case is an exception to this rule; our patient is a stout, plethoric woman, of a highly excitable and inflammatory habit. She has a child at her breast: but, although the bowels of the infant have been disordered by the state of the mother acting on the secretion of the milk, yet there is no eruption on the child. There is no reason for supposing that any of the varieties of Psoriasis are contagious. I have known instances of *P. inveterata* of long standing, where a discharge from under the diseased cuticle existed, and yet the complaint was not communicated to persons who slept in the same bed with the patients.

In the *P. guttata* and *diffusa*, there is not much itching or tingling in the affected parts; but in *P. inveterata*, the heat and tingling sensations, which are much aggravated by the least friction, are a cause of great uncomfortableness to the patients. In the case before us, the poor woman complains of itching, but not in an augmented degree.

The peculiar form of this variety of Psoriasis at once distinguishes it from all other eruptions; but some of the other varieties may be readily confounded with Impetigo; and still more readily with Lepra, which, however, is perhaps only another variety of the same disease.

With respect to the treatment of this case, the necessity for depletion was obvious; and, in general, you will find it to be requisite in all the varieties of Psoriasis, even when general fever does not exist, if the eruption display an evident inflammatory aspect. After reducing excitement, the next object is to allay the irritability of the stomach, for which purpose I have have found nothing more efficacious than the solution of pure potassa. It may be administered in any vehicle; and although in the instance before us I ordered the decoction of elm bark, yet, I must candidly confess, that I place little reliance either upon it or the decoction of dulcamara, which has been greatly cried up in cases of Psoriasis. Had the disease proved obstinate, or should it return, I should order arsenic, as I have frequently seen very obstinate cases yield to a combination of the arsenical solution and of pure potassa. In general these remedies have not fair play, from being administered in too small doses: in some obstinate cases I have augmented the dose of the arsenical solution to sixty minims, and that of the solution of potassa to eighty minims, three times a day, with the most decided advantage. No external application was used in the present case; and although I have found the ointment of nitrated mercury and tar ointment useful in Lepra after removing the scales, yet I have seldom seen any necessity for their application in Psoriasis, except in those local varieties of the disease, such as *P. palmaria*, *labialis*, and *præputialis*, in which cracks, and sometimes the oozing out of a thin acrid discharge from the fissures, occur.

In every variety of Psoriasis much depends on the diet of the patient: it should consist of milk in all its forms, with an occasional moderate allowance of light plainly-cooked animal food; but all salted, spiced, or stimulating meats, in particular pork, prove hurtful; shell-fish also, and perhaps all kinds of fish, should be set aside; and every description of fermented liquor strictly interdicted. So necessary is attention to diet, that, in mild cases of the disease, nothing farther is necessary than a moderate bleeding, with low diet, and a short course of solution of potassa. As a general rule, in all cases in which alteratives, which are all more or less excitants, are indicated, every other stimulant should be withdrawn.

HOTEL DIEU.

Clinique of M. Dupuytren.

Cases of Burn.

The young Egyptians went round the wards this morning (Nov. 13,) after M. Dupuytren; and it so happened that there were several interesting cases presented to their notice. Among the first were two cases of extensive burn. "Not a year passes," said the Professor, "and especially about the setting in of winter, that we have not many cases of this kind. People will be so imprudent as to use chafing-dishes in small unventilated apartments; they become asphyxiated; their clothes catch fire; and if they escape with life, it is at the expense of dangerous burns inflicted during their insensibility." This was exactly the case with the first female now visited: she took a dish of lighted charcoal into her little chamber, which was scarcely eight feet square, and held little more than her bed; there was no fire-place or chimney; there were simply a door and window, but both of them closed. She was soon suffocated, and was severely burnt before assistance was obtained.

The chief lesion was on the right thigh and ham, where there was a large eschar above ten square inches.

M. Dupuytren ordered bleeding and antispasmodics, with compresses of cerate to the part—cataplasms.

ENCOMIUMS OF OUR CONTEMPORARIES.

" Laudari a laudatis viris."

It is seldom we trouble our readers with our own praises—even when they come upon us from the most respectable quarters; but really the following commendatory effusions are so flattering to our vanity, that we cannot deny ourselves the pleasure of putting them on record. The learned writers of these editorial panegyrics must surely have held council together how they might best do us honour. How sweetly do they unite in concert like Duke Theseus' hounds—

" matched in mouth like bells,
Each under each !"

Lancet, *Nov.* 17.

" Dr. Elliotson's nerves are finely strung, and he entertains too delicate a sense of honour to permit even such a contemptible creature as the fabricator of the *mock Lancet* of the BATS, to charge him with misrepresentation, without rebutting the calumny, and casting back into the teeth of the slanderer the disgrace and ignominy consequent on the exposure of his falsehoods. The generous pupils of the London University, sensibly alive to the highly honourable feelings of their professor, intimated their intention of visiting the reviler with some marked signal of their indignation and contempt. But Dr. Elliotson calmed their excited feelings, and set the question at rest, so far as the University is concerned, by some explanatory remarks addressed to his class on Monday evening last. If Dr. Elliotson had been the aggressor, he could not have shown a greater anxiety to stand well with his colleagues and the pupils at the University. As the party attacked, he has displayed in an eminent degree the best qualities of an honourable mind. Dr. Elliotson, however, ought not to forget what sort of being is the object of his censure. If a toad were to obtrude itself in the path of a lion, and the *monarch of the forest* were to half crush it to death, the reptile would have no just cause of complaint."

Medical Journal, *Nov.* 17.

" The liberal spirit which breathed through every line of Professor Elliotson's Introductory Lecture at the London University, and which we eulogised in the strongest terms, excited the ire of that addle-pated imbecile, who ministers to the depraved taste of the corruptionists and pluralists in the medical profession. Nothing could be so perfect as the London medical schools; there was no need of a University or a King's College; both were vituperated week after week; the present teachers in London formed a great university, which was only equalled in the celestial empire; when most unluckily for this visionary institution, Professor Elliotson had the unfeeling hardihood to demolish it as if by magic. The architect saw all his hopes vanish into thin air, and then turned round on their *destroyer* and grossly misrepresented him. This led the independent Professor to withdraw his support from a periodical which would have long since ceased to exist, had not his lectures appeared in it. But he now declines his sanction to the publication of his lectures, and thus seals the doom of the most stupid, partial, and unprincipled periodical, that ever depreciated the medical literature of this country."

The " monarch of the forest" must needs be proud of so noble a pair of jackals.

DR. ELLIOTSON.

We have received various letters on the subject of our discussion with this gentleman: some of our correspondents request that if he should write again, though in another journal, they may be made acquainted with the tenor of his remarks. The *Lancet* of this day (Nov. 24,) in which any such paper might have been expected, contains no rejoinder. Under these circumstances we deem it but fair to decline inserting any of the numerous letters we have received on the subject.

NOTICE.

We have complied with Mr. Woolrich's request.

ON THE

THEORY AND PRACTICE OF MEDICINE;

Delivered at the London University,

By Dr. Elliotson.

CUTANEOUS DISEASES.

PUSTULÆ.

VARIOLA—SMALL-POX.

Etymology.—I will now consider a very important pustular disease, called in English *small-pox*, but in medical latin *variola*. I understand that the word pock, or pox, is of Saxon origin, and comes from the word *poccadl*, which is derived from the word *pocca*, a bag or pouch; or *pochcha*, meaning the same thing—a little bag. The term *small* was added to it in the third or fifth century, I suppose to distinguish it from the great pox. Some etymologists say it is called *variola* from the word *varius*, spotted, or else that it comes from the Latin word *varus*, a pimple. How the point is to be settled I do not know. The disease is called in Spanish *viruelas*, and some derive this from the Latin word *virus*. Such is the origin of this mass of corruption—like the disease. Mr. Moore has written an admirable History of the Small-pox and Cow-pock, both of which works are exceedingly interesting and well worth reading. He says that the word *variola* was first found in an old Saxon Chronicle, ascribed to Marius, Bishop of Vaux, in Switzerland, who says that a violent malady broke out in Italy and France in 570, attended with purging.

Symptoms.—Now the disease before the eruption appears is marked by certain premonitory symptoms. The patient first of all is generally seized with languor, drowsiness, vomiting, pain of the head and loins, just as might occur in any other fever. Here is the head affected—drowsiness and languor; here is the stomach affected—vomiting; and here are the loins affected, which almost always occurs in common continued fever. There is pyrexia, universal feverishness, quickness of pulse, and also tenderness of the epigastrium; but the pain in the loins and the tenderness of the epigastrium are frequently most intense, being very marked in this disease.

After these symptoms have prevailed a day or two, there appears about the third day, first on the face, and then successively throughout the body and extremities, small red spots—*papulæ*, and these rise into elevated pimples, and these again into hard tubercles, in the common acceptation of the word. So that first of all you have mere red spots on the skin, these spots arise into what are commonly called *pimples*, and then these pimples become very hard—*tuberæ*. These pimples become pellucid, and on the fifth day, counting from the first attack of feverishness, headache, and so on, they become pustules: from being pellucid they have purulent contents, opaque and white; and those which are large, are at first generally depressed in the centre. This is worthy of notice: they are not perfectly filled at first, but are filled in the circumference more than in the centre.

Now when this eruption is taking place, if the individual be an adult, there is frequently a great tendency to profuse sweating, and if the patient be a child, there is a great tendency to epileptic fits. It is said that one fit forebodes a mild disease, whereas several forebode a severe disease; but I should suppose that if the child had no fit at all it would forebode something better still. Where there is but one fit, there is so little mark of severity of dis-

ease that it often has been supposed a favourable symptom, but I should think it is not so favourable as where there is no fit at all.

On the eighth day—counting always from the first—if there be much eruption, the face swells from the inflammation. If the disease be pretty severe, the cellular membrane beneath falls into more or less irritation, and secretes abundantly, so the face swells on that account: the same circumstance causes the eyes to close, and the continued extension of the irritation causes the mouth to run, and the fauces to inflame. On the eleventh day the pustules are at their height, as full and as numerous as they will be; and the swelling of the face, the running of the mouth, and inflammation of the fauces subside; and then the hands and feet swell—first the hands, and afterwards the feet. You see that the irritation has diminished above, where the disease first appeared, and has extended below. The spots spread down the body and arms towards the hands and feet; and as these parts suffer the last, so they swell the last; and when the swelling commences, the irritation has already begun to subside in the parts originally affected. The pustules are then said to maturate; that is to say, they grow ripe and perfect. When this general suppuration has occurred and the formation of pustules is perfect, then again a fresh attack of feverishness occurs, and this is called the *secondary fever*. That which occurs in the beginning, ushering in the disease, and continuing for a little time, lessens when the eruption comes out, and is called the *primary fever;* and when the eruption has gone on for a certain number of days, and the general irritation is lessened, then, at the perfection of the eruption, when all the pustules have attained their full development, and each pustule has become filled with matter, and is of its full size, a second attack of feverishness takes place.

When the pustules begin to diminish, and the matter to be absorbed, the common people, especially old women, call it *the turning*. You will continually hear in practice that the disease has turned, and the meaning of that is, that the pustules have begun to subside.

The pustules on the extremities, as I have said, appear later than those on the face and trunk, and their contents, I should also mention, are more limpid: there is not that excessive inflammation there which produces pus, but only a puriform fluid—a limpid fluid rather than perfect pus, and in them the fluid is frequently absorbed altogether without any exudation occurring. In the other pocks, throughout the body and the face, the matter very frequently exudes; but those upon the extremities, particularly the hands and feet, lose their contents entirely by absorption, so that the elevated cuticle remains flaccid and empty. I need not say that those pustules which are on the extremities, coming out last, "turn"—according to the old women's expression—last. The pustules, too, when the matter escapes, generally dry into hard scabs; the matter exudes, a scab is formed of this dry pus, and frequently a little ulceration has taken place, so that a pit is left. The secretion is not merely superficial and cutaneous, but ulceration of the cutis takes place, and even of the cellular membrane underneath, so that marks are left. These pustules are nothing but so many minute abscesses, and of course there is more or less destruction of the parts, and a cicatrix is left on a small scale. If many of these run together, then a person is said to be *seamed:* there are whole tracts of loss of substance.

From the inflammation which affects the eyes, there is not unfrequently in the violent form of the disease albugo left, or staphyloma. Pustules frequently form around the eyes, and on the cornea itself, and there is often ophthalmia; and where there has been a pustule on the eye, it is common, as I have said, to have albugo, and even staphyloma. If you had formerly visited a charity for the blind, you would have seen a great number of the inmates rendered so through the small-pox, and having staphylomatous eyes. When the disease is over it frequently leaves scrofula; persons may have enlarged glands of the neck, or they may have enlarged mesenteric glands, or you may have phthisis. Frequently it leaves rupia and ecthyma; diarrhœa too is not unfrequently left after it, and the mucous membrane of the intestines sometimes falls into chronic inflammation.

You will observe, that if I enumerate again the days on which the changes take place, they are first according to the tertian type, and then they assume the quartan type. The day on which the disease begins is the first day; then on the third—that is according to the tertian type—the pustules make their appearance; then, still according to the tertian type, on the fifth day perfect pustules are formed. The eruption begins as a little spot; this is succeeded by an elevation, which afterwards becomes hard, and this contains something limpid; and then, on the fifth day, the contents become perfect pus. From that time the quartan type commences; it is on the eighth day, if there be much eruption, that the face swells, the eyes

close, and the mouth runs; and on the eleventh day the pustules are all at their height, and there is no farther aggravation of the eruption. This enumeration will assist your memories.

Varieties.—Now the disease is generally divided into two varieties, the one called *distinct*, and the other *confluent*. In what is called discreet, or distinct, the pustules do not touch each other; the pyrexia, or feverishness, is of that kind called inflammatory, and is attended with a pretty strong pulse, and great heat of the body. The pustules are comparatively few in number, and are all detached. Perhaps there may be very few pustules, only one, two, three, half a dozen, or a dozen; but if there be more, still they are detached. They all look healthy, and have a rose-coloured base, shewing a healthy inflammation; their contents are good, laudable, praiseworthy pus. The fever in this form of the disease lessens when the eruption comes out, and when the eruption is complete, the feverishness is nearly gone. The disease is mild but perfect.

In the other form of the affection, however, which is called *V. confluens*, the pustules are very numerous, and run together; the feverishness is infinitely more violent, and rather of a typhoid character; the pulse is not so strong, the patient is exceedingly weak, and there is delirium. There is often such a violent affection of the head that it produces coma; and the eruption not unfrequently begins early—there is such violence of the disease that it begins even on the second day. The pustules are not only far more numerous, but they are smaller; they are not well developed, well formed, well fed pustules; on the contrary they are flaccid, and not filled as they should be. Their quality also is bad; for instead of containing a creamy laudable pus, the contents are brown, perhaps thin and serous, and perhaps there is a brownish ichorous fluid rather than genuine pus; they not only run together, but, from not being well filled, they appear more or less flat. The feverishness in this form is very little lessened on the appearance of the pocks, and at the end of the eruption it is aggravated very much; secondary fever of a very violent character comes on. The symptoms occurring in other parts are also very severe; there is much more ptyalism, much more running of the mouth, much more inflammation of the fauces, than in the distinct form; and in infants there is sometimes violent diarrhœa. In this latter instance the lower part of the alimentary tract suffers great irritation. Frequently too there are petechiæ, vibices, and ecchymoses, between the pustules; there are, in short, red, dark-coloured spots, of various sizes. Sometimes there is bloody urine, and sometimes blood appears in the motions. There is an intolerable stench, the secretions are very unhealthy, and there is an exudation all over the body, so that the person emits a very offensive smell. Now and then patients labouring under this form of the disease die rather suddenly—they suddenly sink. The consequences of this species of the disease too are more severe than in the other form; in fact it is V. confluens that for the most part leaves such terrible consequences, as blindness, phthisis, and diarrhœa, the latter of which ends in ulceration of the intestines.

It is said, but I do not know the fact from experience, that negroes generally have a horny, warty, small-pox, the eruption being minute in size—that is to say, fibrin is effused into the pocks, which gives them a hard warty appearance.

United with other diseases.—The disease rarely, comparatively, occurs more than once during life; and although we may all see instances of its secondary occurrence, yet these are exceptions to the general rule. Like measles, however, and scarlatina, it may be had more than once, and it has been known to occur simultaneously with measles and cow-pox; it has existed conjointly with them in the same person. You know that it was a dogma of John Hunter (an assertion without proof), that no two specific diseases could exist at the same time in the same body; but it is untrue. You will see persons labouring under itch and syphilis at the same time; and there are plenty of instances on record of small-pox co-existing with measles and cow-pox, though in general one disease runs its course in the body, and then the other. It is mentioned in the Edinburgh Medical Commentaries, that measles and small-pox occurred simultaneously in sixteen children. Out of forty-three children who were inoculated, sixteen were at the time labouring under measles, and both the diseases went on together. This occurrence took place at the Foundling Hospital in Dublin.

Causes.—The cause of this disease is, I believe, in most instances a specific poison generated by an individual labouring under the disease. Children sometimes have it without there being any possibility of tracing infection; but for the most part we can do so. It is a disease which is infectious as well as contagious. There is no occasion to touch the patient labouring under it, or any thing that he has touched; to be near him is quite sufficient. One reason for thinking that it always arises from another individual labouring under it is that in Denmark the

disease was made to disappear for many years, by practising vaccination on every individual; but at last the inhabitants grew careless, and being visited by persons labouring under the affection, it again broke out. If, however, the two diseases be the same, the argument falls to the ground; if the cow-pox be merely modified small-pox, then these are merely instances of the disease occurring but once.

Liability of all persons to the disease.—Almost all persons are liable to take the disease—so liable, that it is hardly right to say that a predisposition is required. From the few there are who escape if the poison be applied, it is a better mode of expression to say, with regard to those who will not take it, that they are *indisposed* to it, than to say that they are *not predisposed* to it. The only thing wanted is, the absence of an indisposition. Persons have been known to escape this disease for forty or fifty years, and then have it. The same circumstance occurs with regard to hooping-cough and other contagious diseases.

It is supposed that the predisposition to it, if I may use such a word, is strongest in early life; but I believe I mentioned formerly, that this is hardly proved, because most persons take the disease, if they have not had the cow-pox, in infancy or childhood, and therefore there are but few adults left to have it.

Occurrence in the Fœtus.—Like syphilis it may occur in the fœtus. The mother may give syphilis to a child in utero, and also the small-pox, and in the latter affection it is singular that the mother may communicate it to the child without having it herself. Dr. Jenner published, in the first volume of the Medico-Chirurgical Transactions, instances of two women who, when pregnant, were exposed to the contagion of small-pox a few days before delivery. Both women were, I believe, exposed to it by infection; but one woman had had the affection formerly, and therefore she had acquired immunity; and the other had been inoculated, so that she also had acquired immunity. Neither of the mothers had the disease a second time, and therefore they served merely as transmitters of the poison to their children. In the one instance the disease appeared in the child on the seventh day after birth, and the other female brought forth a child covered with the small-pox. Dr. Mead, in his Treatise on Variola, you will find, mentions a similar fact. However, this has not always been the case, for Sir George Baker mentions that two women, who took the disease during pregnancy, brought forth children perfectly healthy, and they never had it till they were inoculated, which did not take place till they were three years old. I do not know whether a woman can give syphilis to a child without the disease affecting herself—whether she can have the poison conveyed to her system by a man, and yet have no symptoms of the disease, and nevertheless produce a child affected with syphilis. In my experience, wherever syphilis has appeared in a child at its birth, or soon afterwards, the mother has shewn syphilitic symptoms either then or soon after. It is, however, to be remembered, that we have no immunity from syphilis. We have immunity from small-pox and cow-pox, in consequence of the disease having occurred previously; and when immunity can be produced from a poison, then you see that the system may transmit it, being yet perfectly safe itself.

Period of Incubation.—As to the period at which the disease appears after exposure to the poison, the late Professor of Botany in Edinburgh (Dr. Rutherford) used to say that a party of soldiers were exposed to it in the natural way, and that the interval between their exposure and the appearance of the disease varied from twelve to fourteen days. Dr. Fordyce, who paid great attention to this subject, said that the period which I have now stated was the common interval: however, it is sometimes certainly known to come out earlier.

Resemblance to other Infectious Diseases.—Like other infectious diseases, it is very frequently epidemic; and it is more frequently so at the vernal equinox than at any other time. It is said, by Sir Gilbert Blane, to resemble measles and hooping-cough, in being more fatal during an epidemic than at any other time. After it has been absent some time, it is also more severe than at other periods. It is also observed to be like all other epidemics in another respect: those who have it first, have it the most severely.

Opinions of the Ancients.—It is said that, by the ancients, this was not known to be a contagious disease; and, indeed, they confounded measles, scarlet fever, and small-pox together. Rhazes, an Arabian, and one of the eldest writers on the subject, ascribes it to the fermentation the blood undergoes when the youth is becoming a man. Sydenham, who has given so perfect a description of small-pox that it can never be surpassed, had no idea that it was a specific contagion. He thought that scarlatina was most prevalent in the autumn, and he ascribed it to a moderate effervescence of the blood, arising from the heat of summer. He entertained much the same opinion of measles and small-pox. I believe I mentioned that Gadbury, the astrologer, wrote, without fear of being laughed at, that plague was not more in-

fectious than small-pox. Then another worthy man, Etmuller, who is much quoted by German writers, says, that no doubt small-pox and measles take place from the child drinking morbid nourishment in the uterus, and then, after birth, sucking it in the milk. He says, " it is not probable that those who assert that measles and small-pox arises from copulation after conception has taken place are correct, and therefore I suppose that the foundation of measles and small-pox lies in the milk which the child takes first when in utero, and then afterwards when born." It was distinctly declared to be contagious by Boerhaave, who mentioned contagion as the only cause of it.

Contagion and Atmospheric Influence.—But though nobody now doubts that it is contagious, yet its spread is greatly influenced by certain states of the atmosphere. Violent cold will check an epidemic small-pox: though it is an epidemic disease, yet a low temperature of the atmosphere will check it. The wind called *harmattan* stops small-pox just the same as plague, and it is said to prevent the effects of inoculation; so that if you inoculate when that wind is blowing, it is a fruitless task. I mentioned this particular circumstance when speaking of contagion in general, in order to shew what influences are exerted on it. Sir John Pringle says that the small-pox was carried by some troops, on one occasion, to the camp, but, in consequence of some peculiar state of the atmosphere, it would not spread. Van Sweiten mentions a similar fact. Dr. Odier, a physician at Geneva, mentions that when this disease was not epidemic it would not spread by contagion. When children had the disease by inoculation, if they were carried about the streets and brought into contact with other children during the eruption, there was not a single instance of a child catching the disease. Sir James M'Grigor says, that when the disease was prevailing extensively at Bombay, in the neighbourhood of his barracks, although there was the freest communication between the inmates of the barracks and the surrounding population, yet no person about the barracks caught the disease. Burkhardt, the traveller, says that small-pox was never known to visit the Wadykenous, which is a narrow shore leading from the Cataract up to Korosko; yet it was well known at Derr, a place situated a little distance off, and much dreaded. We must, when we are considering whether a disease is contagious or not, set no value upon the circumstance of certain states of the atmosphere putting a stop to it. Contagious diseases, in this respect, are in the same predicament as those which depend altogether upon atmospherical influence. That it is a contagious disease cannot be doubted, when you reflect that it will habitually occur to children when their parents will not allow them to have the cow-pox.

Relative effects of Inoculation and Vaccination.—Small-pox is communicated artificially by inoculation, because the disease which then arises is much more mild than that which occurs naturally. The effect of inoculation is to lessen the number of pustules, and thus to lessen the general violence of the disease. The effect of vaccination upon the disease if it do not prevent it altogether, is rather that of lessening its duration. Inoculation produces the disease with a far smaller number of pustules and less general irritation; whereas, if a person have small-pox after vaccination, the disease goes on in the usual way for a certain time, and then all at once the feverishness ceases, and there is rapidly an end to it. It will terminate, in fact, on the sixth day, instead of the eleventh.

It is found also that the disease appears much more quickly when it is communicated by inoculation than when it is communicated naturally. The affection usually appears on the seventh, or at the latest upon the eighth day, when it is communicated by inoculation; whereas, when it occurs by infection, it is generally from the twelfth to the fourteenth day before it appears;—and consequently you may, by inoculation, be before-hand with infection. If a person have been exposed to the infection of small-pox, and has a great chance of having a severe disease, it is right, if you do not vaccinate him, to inoculate him immediately; because you then produce the disease more quickly than it would otherwise occur; the artificial form gets the start of the natural, and the patient has the artificial disease instead of the natural. Dr. Fordyce also mentions, that the quantity of matter applied greatly influences the severity of the disease: he says, that if you introduce only a small quantity of matter, a less severe disease is produced than if a considerable quantity be employed. On this account, the quantity of matter should be as sparing as possible; it should only be just sufficient to produce the disease. In cow-pox, however, a different rule must be observed; because the object, in that case, is to have the affection as complete as possible, and therefore a considerable quantity of matter must be introduced; and you must not be contented with making one insertion, but you must make several. I wish you to remember, however, that, in small-pox, the object is to have the disease in the mildest way possible, and therefore the

smallest possible quantity of matter is to be introduced.

The fact of inoculation rendering the disease milder, appears to have been communicated to the Royal Society of Edinburgh in the eighteenth century, and the knowledge of it to have been brought to England from Constantinople. The knowledge of this fact is said to have existed in China and Hindostan for a great number of years. The Chinese were in the habit of placing the crusts taken from small-pox patients in the nose, having first frequently kept them in jars for some years; sometimes they reduced the crusts to powder, and made the children snuff them up;—this was called *sowing the small-pox*. The Brahmins are in the habit of scratching the surface of the skin, and then binding upon the scratch a piece of cotton moistened with the pus. It is said that a particular caste has the charge of this practice. They, however, prepare the patients for this process by some months' abstinence, from even milk and butter—and this would be pretty low diet, they having no animal meat at any time. This mode of inoculation appears to have been long practised in Persia, Armenia, Georgia, and Greece, but its origin is unknown. Some imagine that it arose in the deserts of Arabia, where there were no physicians or priests—nothing but old women, the knowledge of the fact being acquired by the vulgar. However, the practice appears to have been known an immense time in the provinces of Italy, in France, Germany, Sweden, Denmark, and even in Great Britain, among the peasants. In the north of Scotland the people were in the habit of giving the children the disease by putting them to bed with others labouring under the affection, or tying threads soaked with pus upon their wrists. But although it was known in this way among the lower orders, (just as we shall see was the case with regard to cow-pock preventing small-pox,) before the enlightened part of the public were aware of it, the practice came to us ostensibly from Constantinople. Dr. Timoni wrote to Dr. Woodward on the subject from Constantinople, and the letter was published in the Philosophical Transactions the year after. Pylarini, a physician, also wrote on the Turkish practice, and sent his communication home in 1715, and this was likewise given to the public in the Philosophical Transactions. Lady Mary Wortley Montague was at Constantinople with her husband, who had been appointed ambassador to the Ottoman court, and she there learned the practice, and being a couragious woman, tried it, with success, on her own son. On her return to England she had her daughter inoculated. Caroline, Princess of Wales, wished to have her children inoculated, but was desirous that the experiment should first be made on six felons in Newgate. She obtained the consent of George the First, and the operation was performed. Five of the felons did well, but the sixth did not take the disease, having in fact previously had it; but, on account of being inoculated, they were all saved from hanging. Inoculation was now thought favourably of in England, and it appears that in the first eight years, 845 persons were inoculated, only 17 of whom died: at Boston, only 1 out of 45 died.

Of course, as this was a new practice, it excited opposition. Whether the practice was good or bad, being new was sufficient to account for this; and many clergymen and dissenting ministers raved against it from the pulpit, and called inoculation the offspring of atheism: those who performed it were called sorcerers, and the whole thing was said to be a diabolical invention of Satan. Others, however, were of a different opinion, and Bp. Maddox and Dr. Doddridge defended it, and in doing so employed scriptural quotations. You know that the devil can quote Scripture to suit his own purposes, and therefore it was very fair for good men to quote Scripture too. However, the reasonable side of the question at last prevailed.

Then, after a time, the practice was nearly relinquished throughout Europe, just as we saw was the case with regard to the use of Peruvian bark. After the practice of exhibiting bark had been approved, the good opinion formed of it was entirely lost, so that it became a *drug* in the market; and inoculation was almost disused in England from 1730 to 1740, and in France it was absolutely forbidden.

The truth, however, was, that inoculation caused a great loss of life: it saved the lives of a great part of those who were inoculated, but it kept up the pestilence to such an extent, that far more caught it than otherwise would have done so, and it increased the general amount of the disease.

With regard, however, to the success of the practice, I may remark that frequently those who were not medical men, were the most successful. Some Carmelitish friars inoculated the Indians of South America very successfully; and the most successful inoculators in every part were non-medical men. A planter, at St. Kitt's, is said to have inoculated 300 of his slaves himself, without having lost one.

Medical men made a great preparation for inoculation by purgatives, emetics, and various drugs, and employed all these things also in the course of the disease.

They likewise confined their patients to bed, and kept them in a hot room, with a view to encourage perspiration. This practice aggravated the feverishness, and increased the mortality from the disease. Of course the disease was also kept up by so many being inoculated. Great fury prevailed against it, when in 1754 the London College of Physicians published a declaration in its favour.

Inoculation, however, met but with slender success till the time of a person named Sutton. This quack, however, used purgatives and common-sense treatment, and succeeded wonderfully, so that he spread inoculation more than the College of Physicians and all the doctors together. Sydenham practised free ventilation and refrigerants; but Sutton omitted the opiates which Sydenham was in the habit of giving, and gave calomel and tartar emetic. Sutton also restored the Turkish practice of making only a slight scratch with a lancet. The practice, indeed, fell very much into the hands of quacks. Medical men ceased to have recourse to it, but quacks took it up, and endeavoured to turn a penny by it.

Such, gentlemen, is the curious history of inoculation. Its efficacy was first doubted; the practice was afterwards approved; then violent disunion and party feeling was excited—the most virulent abuse was poured forth, and the thing dropped altogether. Then it was taken up by quacks, and quacks were frequently much more successful than the doctors, by not employing a number of medicines, which did harm.

When inoculation was first practised, it is said that only one patient out of fifty died; but now, not above one in two hundred die, and some have calculated not more than one in five hundred: whereas the mortality from natural small-pox was as much as one in six, where medical aid was rendered, and where there was no medical aid the mortality was frightfully great; and, in fact, at one time nearly all died where medical aid was not resorted to. The annual deaths from small-pox in England, during thirty years of the last century, were from 34,000 to 36,000. Before vaccination was practised, and after inoculation was established, one child in seven, throughout Russia, is said to have died from small-pox; whereas Spain, which did not trouble herself about inoculation, suffered far less than any other country, the disease having been kept up in others by inoculation.

Treatment.—In regard to the treatment of the disease, there is nothing peculiar in it; it is only the treatment of any ordinary fever. The utmost cleanliness should be observed; the patient should have plenty of clean linen; and mild antiphlogistic diet will be proper—at least in the first instance. There is no harm whatever in cold or tepid ablution, provided the body is hot. Some say that they have stopped the disease by affusion; but you may have recourse to tepid ablution if there be any objection to cold; and as the stench is very great, it would be well to wash the patient with a solution of the chlorides, and use them freely around the bed.

Now and then it may be proper to bleed. The head is sometimes so much affected that general bleeding may be premised in the case of adults; or at any rate the application of leeches to the temples. The pain in the loins, which characterizes the disease, generally goes off very soon, but the oppression of the head may require local bleeding, or, in adults, general bleeding. Usually the latter is not necessary, but every practitioner must judge of that for himself. Purgatives are proper; the bowels should be kept freely open. By cleanliness, the employment of the chlorides, purging, bleeding (general or local), and low diet, the disease will be got through in the most favourable manner.

But after a time, if debility come on, especially if the patient's pulse become weak, or if the pustules be not well filled, and there be no violent local disease; if, in short, there be any signs of debility, and of the disease assuming a typhoid type,—then wine and stimulants should be given. Sydenham was in the habit of giving opium at first, and I must say I think in that respect his practice was bad. You may consider that, in confluent small pox, when the patient is covered with pustules, such an immense number of little abscesses are equal to one large one. There is universal suppuration of the surface, and the patient requires to be supported just as he would in the case of a common abscess. It is frequently necessary, too, towards the close of the disease, to give wine, ammonia, and sulphate of quinine, with good nourishment. But there may be, on the other hand, such sharpness of the pulse, and such general irritation, that measures of this nature are improper; and you must be contented with giving the patient, perhaps, no more than milk or whey, and keep him cool. There is, as I have already said, nothing peculiar in the case; it is only the treatment of fever.

Some have advised (it is an old practice, but it has been talked of again lately) letting the matter out from each pustule: you might do this with a needle; and it is said that there is some utility in the practice. Any inflammation that may occur, whether in the head, eyes, bronchiæ, or intestines, requires to be at-

tended to. You must constantly be on the look out for these affections; but the treatment is certainly to be conducted altogether on general principles. You have only to remember that you are treating, not merely an inflammatory, but a specific disease—a disease attended by suppuration on the surface. Fresh air, cleanliness, and the chlorides, are very proper, just as in other cases.

Affection of the Larynx and Trachea.—I omitted to mention that, among the internal affections of the mucous membranes, that of the larynx and trachea frequently suffer much; and many children die from the upper part of the trachea being blocked up. If you look into the larynx of those who have died of small-pox, you will find it filled with a thick tenacious mucus, and much swelled. I believe many children die in small-pox really from the larynx being obstructed in this way. It is a point to which Mr. Alcock, the surgeon, has particularly attended; and in consequence of having had my attention directed to it by him, I have frequently examined the larynx of children who have died of this disease, and its state has been such as to astonish me. There has been great inflammation, and such effusion of thick stuff as very nearly to block it up.

[The last part of the above was given as the first portion of the next lecture, but we have thought it better to insert it here, so as to complete the subject.—E. G.]

CLINICAL LECTURE

UPON

THE LARYNX—LARYNGOTOMY—AND THE CIRCUMSTANCES UNDER WHICH THAT OPERATION OUGHT TO BE PERFORMED,

Delivered at the Middlesex Hospital,

BY SIR CHARLES BELL.

SIR CHARLES BELL began his course of clinical lectures by presenting a classification of all the cases which were then in the hospital. He read a short account of these under their different heads, and pointed out, in each department, the proper subjects for the students' attention, and the mode in which they should prosecute their studies. This, which was intended for a single lecture, was extended to five, in consequence of the rule by which the lecturer guided himself, of alluding to all consultations and operations immediately after they occurred. The operations of hernia, of trepan, of amputation, and of laryngotomy, were the subjects thus casually introduced: and we select the last.

Case.—Jeremiah Kentish, aged 60, a labourer, was admitted on the 23d October, by Dr. Watson, with general anasarca, his legs and thighs being more swollen than the rest of his body. His respiration was difficult, and attended with a wheezing sound, audible at some distance. He complained also of cough, and of inability to lie down in bed; and stated that during the preceding night, he had been nearly "choked." His pulse was hard, but not full. His bowels were reported regular; his urine scanty, though he had a frequent desire to void it.

He declared that the swelling came on suddenly, only five or six days before; that at first his face was so much swollen that he could scarcely see; that he had no previous illness, except a recently slight shortness of breath; and that he knew no cause of the attack.

16 ounces of blood were directed to be taken from the arm, or more, according to the effect of the bleeding; and 8 ounces from the chest, by cupping.
4 grains of calomel to be given immediately; and a senna draught four hours afterwards.

24th.—He was bled from the arm to 24 ounces, with very little relief to his breathing. The blood in some of the vessels only is buffy. He now says that he lost a pint and half of blood the night before his admission. His bowels have been thoroughly purged. Urine plentiful, acid, and with a pink sediment. The anasarca has almost entirely disappeared. He is now sitting up in bed, breathing with great labour, and with a loud stridulous noise, which accompanies both inspiration and expiration: he refers all his uneasiness to the larynx, and to the ensiform cartilage. He swallows with difficulty, and every effort of deglutition excites a fit of choking with cough. There is no morbid appearance to be seen in the fauces. He has expectorated a small quantity of viscid yellowish mucus. Every part of the chest sounds well on percussion, and the murmur of respiration can every where be heard, almost drowned, however, in the louder laryngeal noise.

He vomited freely soon after swallowing a scruple of ipecacuanha. This was followed by no improvement.

12 ounces of blood to be taken by cupping from the back part of the neck.
3 grains of calomel to be given every three hours; and $\frac{1}{3}$ of a grain of the acetate of morphia immediately after the cupping.

During the afternoon the steam of hot

water was inhaled for some time, and 20 leeches were applied near the larynx.

In the evening the difficulty of breathing increased still more, and each act of respiration was attended with a loud croupy sound: his countenance was now anxious and ghastly, and his pulse was less firm. It was Dr. Watson's opinion that he would probably not survive the night, unless the operation of tracheotomy was performed, and that his general condition was such as to afford good ground for hoping that his life might thus be saved. Between 8 and 9 o'clock, he sent to request Sir Charles Bell's assistance, who immediately attended at the hospital. Mr. Joberns and Mr. Arnott were also present; and all agreed upon the propriety of proceeding to the operation forthwith.

Although the patient was placed in a bed at the further extremity of the ward, the crowing sound of his breathing could be heard before entering. Upon approaching him, he was seen sitting forwards, moving with restlessness from one side of the bed to the other, and throwing his arms about, as if seeking for some new place of support. His countenance was pale and expressive of great anxiety, and his lips were of a livid blue colour. His shoulders were in continual action, being alternately elevated and depressed to the utmost; and the prominent larynx moved up and down in a remarkable manner, corresponding with the laboured heaving of his chest. He spoke with sudden, and as it were, convulsive efforts, earnestly expressing how thankful he should be to have the obstruction of his breathing removed, and said that in every other respect he felt easy, being free from pain except at one part, pointing with his finger to the lowest part of the larynx.

It was remarked how very short the space between the larynx and the sternum was, and that when the larynx was drawn down by the action of its muscles, there was scarcely half an inch between the upper part of the cricoid cartilage and that bone.

The operation was begun by pinching up the skin over the space between the thyroid and cricoid cartilages, and then dividing the fold thus made with the knife. Two small arteries, which threw out a stream of blood more than two feet, had to be secured by the ligature. After dissecting a very little, the point of the knife was thrust into the membrane which joins the fore part of the thyroid and cricoid cartilages, and the blood in the wound showed by its frothiness that the air-passage was opened. The longitudinal slit which was thus made, was enlarged by cutting with the bistoury sideways; and after this was done, it was attempted to introduce a silver canula into the trachea. But as soon as this instrument entered the larynx, a dreadful paroxysm of suffocation was the consequence: the patient gasped, struggled, and drew his breath with a moaning sound, occasionally interrupted for some seconds, as if he were on the point of ceasing to respire altogether; and it was a considerable time before he could be restored from this attack so as to submit again to the operations of the surgeon. It was next attempted to keep the slits of the wound apart by introducing a catheter wire, previously bent upon itself, into the opening; but another paroxysm of suffocation, more alarming than the former, and lasting a greater while, was immediately produced; and the interrupted and vain attempts to express his distress with words, the laborious heavings of his chest, the perspiration starting in drops from his face and brow, all showed the intolerable nature of his sufferings, and how impossible it was to retain such an instrument in the wound. Finding it thus impractible to preserve a tube within the trachea, it was resolved to remove as much of the membrane which surrounded the opening already made in the larynx, as would permit the air to have a free passage into the lungs. Upon commencing to do this, it was astonishing to every one to what a depth the larynx was withdrawn, it being not less than an inch and a half from the surface of the wound. What principally, however, created a difficulty in the object proposed by the operator was, that the inner membrane of the larynx had become so extremely irritable, that whenever it was touched, however slightly, by the hook, the blades of the scissors, or any other instrument, a fit of coughing and an attack of laborious breathing were excited. Besides this, the larynx had a continual rapid movement upwards and downwards, (resembling the incessant rising and falling of the piston of a steam-engine at work:) and thus the depth of the larynx, the extraordinary irritability of the mucous membrane, the constant movement of the windpipe, together with the filling up of the wound with blood, as quickly as it was sponged away, all conspired to make it an operation of great difficulty to remove the angles of the membrane that were left. Another circumstance was observed deserving of attention, since it prevented respiration being performed through the orifice in the larynx: at each inspiration, the lips of the opening, which were seen to be expanded during expiration, became completely shut; and this was obviously consequent upon the thyroid and cricoid cartilages being drawn, by the action of their muscles, more closely together during the act

of inspiration. Sir Charles Bell remarked that the spasmodic action, producing this shutting of the orifice, even caused the cartilage to pinch the point of his finger when it was applied over the part: and it was from observing this fact that to some of the witnesses of the operation it appeared indispensably necessary to have a tube inserted into the windpipe. The cricoid cartilage was so hard, that it was supposed to be ossified: and whenever the bistoury or strong scissors were employed to cut a piece out of it, fresh paroxysms of suffocation were produced. Several loose portions of membrane were removed from the orifice in the larynx, and also those loose portions of the cellular membrane which were in danger of being sucked inwards during respiration were snipped away. Two catheter wires were then employed to hold the integuments apart: this was accomplished by doubling each of the wires, and forming their bent extremity with a hook, resembling that which is sometimes used for holding the eyelids separate in operations upon the eye: one of these hooks being inserted on each side of the exterior wound, and the wires being bent round and fastened at the back of the neck, the surface of the windpipe was kept freely exposed to the air. When this contrivance had been applied for a little, the breathing became greatly improved; and as an indication of the relief which the patient had received, he fell sound asleep. The crowing sound continued, which proved that his breathing was not altogether performed through the wound. An assistant had to be placed behind the bed-chair to prevent the patient's head from nodding forwards in his sleep, which he had already shown deranged the apparatus in the wound. The pulse was 93, and of good strength.

3 grains of calomel to be taken every two hours.

25th.—He passed a tolerably good night, sleeping a good deal at intervals. The aperture is smaller by the swelling of the soft parts. The respiration is carried on chiefly through the wound, but with labour and hissing, and occasional expulsion of viscid mucus. Last night a small portion of his powders was observed to issue at the wound; and the same thing has since happened upon his swallowing milk. He can swallow liquids only; and he experiences some difficulty, apparently, when they are in the act of passing through the bag of the pharynx. The sound over the chest, on percussion, is good: some large crepitation is heard by the stethoscope. The pulse is smaller, and wiry. His bowels have been once opened. He is to continue his medicines, and to take arrow-root and milk from time to time.

Vespere.—He is much more comfortable: a metallic tube has been introduced into the trachea, through which he respires easily. His breathing is attended with but little noise. He has an urgent occasional cough, which is relieved by expectoration of tough mucus, partly through the tube and partly by the mouth. His bowels have been opened five times. His pulse is above 100, small, and sharp; his tongue is clean.

Opii, gr. $\frac{1}{2}$, statim. et adde sing. pulv.
Opii, gr. $\frac{1}{3}$.

26th.—He has passed a good night, sleeping a good deal. The pulse is more tranquil and natural. His tongue clean and moist; his countenance is greatly improved; he has had three stools. An opiate enema was administered. In other respects he is the same as at the former report.

27th.—He has had a good night. He speaks better, but he does not breathe more easily through the natural passage. His gums are tender, and he has the mercurial fœtor. The calomel is to be omitted.

28th.—He is going on well, and his countenance is more natural. A larger tube has been inserted.

29th.—He is improving; the tube has been out for about an hour, and he breathes easily through the wound, which is suppurating. When the opening is closed, he soon begins to be distressed; though he seems to breathe better through the natural passage than he did. The fits of coughing have been less frequent and less violent, and the expectoration less viscid. He asks for more food. The act of swallowing is more easy, but it still produces a little coughing; and a small quantity of the fluid which he takes still passes occasionally by the wound. The pulse is 82, of moderate strength; the bowels are open; his gums are very tender. He is to have three eggs a-day, beat up with his milk.

30th.—He has passed a bad night, with much coughing and expectoration. The tube, by some misunderstanding, has been left out since yesterday morning. A portion of his liquid food still appears occasionally at the wound. The bowels are open; his gums tender; the pulse as before. The tube is to be immediately replaced.

31st.—He has been more comfortable since the tube was replaced, and seems to be much in the same condition as before its removal, except that his pulse is rather more frequent.

Nov. 6th.—The tube has been out since the 3d, and he has continued to breathe comfortably through the aperture, which is contracting. He breathes partly through the mouth, and can bear to have the

wound closed for a little time without inconvenience. His gums are still tender. He sleeps well; his bowels are regular; his pulse is good, and his appetite keen. Occasionally a small portion of his food shews itself at the wound. He swallows much better, and seldom coughs after doing so.

16th.—He breathes through the natural passage, and the opening is completely closed. His pulse is 95. He is somewhat hoarse, and says he has a feeling of soreness in the wind-pipe internally, in the situation of the wound.

Sir Charles Bell began his lecture by remarking, that as it was early in the season, few of the gentlemen had probably advanced so far as to be familiar with the larynx by demonstration, and the older pupils would not be unwilling to hear a short recapitulation of the anatomy. He should therefore give a description of the larynx. This he did, first taking it as a piece of mechanism, consisting of cartilages and muscles, and then he dwelt upon the sensibilities with which it is endowed. It was, he said, a surprising circumstance, that this sensibility, which was a guard upon the passage to the lungs, and without which we would not have a moment's security to life, should become, from the circumstances to which he was about to allude, a cause of death: for if foreign matter lodge about the glottis, though it be quite too small to interrupt the passage, yet will it produce spasmodic stricture. If the morsel be interrupted in the pharynx, the glottis is spasmodically shut; if the surfaces hereabouts be inflamed, the very air itself becomes a source of irritation and spasm; and if ulceration should take place, or coagulable lymph be thrown out, it will cause death, more by exciting the spasm of these muscles than by producing actual obstruction. He then drew a contrast between the condition of the parts as we examine them in the dead body and the actual circumstances in which we may have to operate. It would seem, he said, strange that he should recommend the exercise of the imagination in an art like surgery; and yet some of the most dangerous precepts are to be found in books, because the authors have not set forth the actual circumstances, the scene in which the surgeon has to act, and the condition of the patient who has to suffer. At present he had no occasion to describe to his hearers the actual circumstances, or to excite their sympathies: they had seen this old man, after long suffering, sitting up in bed, incapable of utterance, looking round for aid, gasping for breath, and his hands abroad; his face and neck flushed, and his eyes sparkling.

"You have witnessed," continued the lecturer, "the condition in which you have to operate in these cases. So far from being able to lay the patient down, or stretch out his neck, you have seen how the shoulders, sternum, and clavicle were raised, the head drawn down, and the cartilages of the larynx squeezed together by their muscles. But most of all, it is necessary that you reflect upon the condition of venous turgescence, and, indeed, of arterial action too, which characterizes the parts. I am reminded of this by a circumstance which you see stated in the case: the skin was pinched up and cut across, and this was immediately followed by streams of arterial blood from both sides of the wound. If I had cut upon the thyroid gland, you would have been able to tell me whence this blood came; but these arteries did not belong to branches of the third, fourth, or fifth degree of minuteness—they are not known in your anatomy—they are merely cutaneous vessels; and yet you saw that they both required the ligature. This should teach you to be very observant of the circumstances in which you operate: and you would do well to remember that the veins bleed with unexpected profusion, in consequence of the difficulty of the return of blood into the chest during this condition of obstructed breathing.

There cannot be a greater proof of the suffering and anxiety of a patient with impeded respiration, than the readiness with which he submits to the operation; since it is one which must appear to him of the most desperate nature, and which he has heard of only as the certain means of death. Again: you have seen what has always appeared to me a remarkable phenomenon; no sooner is the breathing made free by your operation than the patient falls asleep. This man, although half a dozen candles were close to his face, and we were, with bloody hands, still actively engaged in providing for his safety, fell sound asleep. Can there be a better proof of his long-continued struggle than this? Can there be a better instance of the value of our profession?

Sir C. Bell then made a distinction of the cases for which this operation requires to be performed *.

In the present instance, where there is no accident, or drawing in of a foreign body into the windpipe, we have to ascertain where the disease is seated; and you may have perceived how my excellent colleague was desirous, by percussion of the thorax, to find whether the lungs were

* See a lecture by him on Tracheotomy, for extraction of a body drawn into the windpipe, in the fifth volume of the Gazette.

affected, or were in any measure the cause of the patient's very obvious distress. It has occurred that the operation has been performed when the impediment to breathing was below the part operated on; and the suffering has thus only been aggravated. The disease in the tube may be venereal ulcer, or scrofulous ulcer and abscess about the cartilages of the larynx; or cynanche laryngea, or cynanche trachealis. The inflammation may have subsided, leaving an œdema of the membrane of the larynx, which is in danger of choking the passage: and all these circumstances are important, since the success of the operation will depend on the temporary nature of the obstruction.

Perhaps the most important question that you can entertain, regards the time when the operation is to be performed. I have known it repeatedly happen that the medical consultants have delayed the operation, in the expectation of the circumstances of the case more distinctly vindicating the propriety of their decision. Observe, then, how a disease, which is local at first, extends its influence to the lungs themselves. The spasm in the larynx, and the laborious respiration, are, at last, attended with effusion into the lungs. Either the mucous secretion in the bronchi is increased, so as to impede the entrance of the air, or the effusion into the cellular texture of the lungs compresses the bronchial cells: however this may be, the effect is but too obvious; we see it in the common inflammatory croup, that the child, which is at first struggling with an obvious difficulty of breathing, and with the face flushed, lies, after a certain time, more composed, with less frequent cough, and with cheeks pale and cold. If in this condition the larynx or windpipe could be relieved, it would avail nothing; the child would not recover; and so I have known the operation delayed in an adult who had cynanche laryngea, until coldness and indifference characterized the condition of the patient; and when the operation of laryngotomy was performed, there was not even a temporary amelioration produced.

On the 17th the subject was renewed, on coming down from the visit to the patient.

You have again seen this man, reduced somewhat and pale, and his voice more raucous than natural, but otherwise perfectly well, and only desirous for more food. The opening is closed; in short, he presents such a contrast to his former condition of agitation and suffering, as must interest you in the practical question. It now appears to have been a case of inflammation of the larynx; and it is possible that much of the difficulty of breathing may have proceeded from œdematous swelling of the membrane. The case naturally recalls to my recollection some other occurrences. Some time ago a man lay in Hertford ward with a disease in the head of his tibia. There was reason to believe that the pains were syphilitic; and you are aware that when this disease has thoroughly affected the bones, mercurial action should be slowly raised, and long continued. He was attacked with mercurial erythema; and, as frequently happens, a blush in the pharynx showed the sympathy of that surface with the general condition of the skin. As soon as this was observed, the treatment was immediately changed; but a night or two after, he was seized with suffocation, and the house-surgeon being raised from bed, thought to relieve him by bleeding. The patient died before the morning. Now although such treatment might account for his death, in the lowness and faintness that accompanies the mercurial action upon the system, yet it appeared from the condition of the membrane of the glottis, as disclosed upon dissection, that we might ascribe his death, with more probability, to the serous effusion and gorging of the membrane of the rima glottidis.

There is another subject which it is my duty particularly to press upon your attention. Many of you must recollect the young woman who lay opposite to the door in Northumberland ward; she was subject to disease apparently of the kidney and bladder, but may have struck you more, perhaps, as being a remarkable example of aphonia. She could not produce the slightest tremor in speaking; her whisper was so low, that it required the nurse to put her ear close to her lips; and what gave unusual interest to her case was, that she had had the operation of laryngotomy twice performed on her. She must have been attended by a ready-handed surgeon; for besides this, she had suffered extirpation of both amygdalæ. Now this girl one night had an attack of difficulty of respiration, amounting almost to suffocation; but this was removed by giving her ether and opium. She had, besides, other symptoms strongly characteristic of hysteria; and I confess to you, that my conception altogether of this case was, that the operations had been performed without necessity. I remember to have been sent for to perform the operation of laryngotomy in a woman, whom I found struggling in an hysterical paroxysm. The next morning she breathed and spoke perfectly well, but could not pass a drop of urine. Now these are circumstances occurring under your own eye, which I have no doubt will persuade you, that discretion and the power of discriminating, are above

every thing necessary in the practice of your profession. And here let me point out to you a paper in the last volume of the Medico-Chirurgical Transactions, by Mr. Wood, as conveying a great deal of information upon this subject, and as an example to you. He had been well educated in anatomy and pathology; but not satisfied with that, as has been too much the usage here, he has had recourse to books, and has furnished us with a paper well supported by authorities and sound argument. This is becoming in young men when they write on practical subjects; and nothing can be more ridiculous than the contrary mode of proceeding—when you find men, in the first years of their practice, dictating to the whole profession. You will hear with regret that this young author, who promised so well, has very lately died of cholera.

Let me now say a few words upon the operation. The perforation of the tube, in this case, was made in the membranous space between the thyroid and cricoid cartilages; but I must acknowledge, that when there is disease in the larynx, it would be well if the operation could be performed lower down. Let us not, however, conceal from ourselves the difficulty of doing this. If you cut upon the fore part of the trachea, you have a deluge of blood from the thyroid gland or guttural veins; and you must suspend the operation or use the actual cautery; and unless this precaution be taken, that may happen in your hands, which has happened again and again, that the patient has been suffocated—drowned, I may say—in his own blood. After reading the case, I need not point out to you how much the sternum is elevated, and the larynx drawn down—how the trachea is sunk, or drawn backwards—how deep and confined the whole space is; and it is these considerations which suggest to me a slight change on the mode of operating. If you see reason for operating lower than the part perforated in the present instance, instead of cutting with the knife carried longitudinally on the face of the trachea, where blood flows at every touch, clear the convexity of the cricoid cartilage, and keeping close to its surface, the firm cartilage being your guide, separate the soft parts, pushing them downwards off the front of the tube. Having done this, perforate, with the knife transverse, between the cricoid cartilage and first ring of the trachea. If blood should be in the wound at this time, it will not be drawn into the windpipe, because the slit which you have made in the tube is not open. Through that slit I would have you introduce the canula; but to do this the canula must be prepared. To have a sharp stilette in it is not without danger; for you must recollect that it is on record, that, in attempting to perforate with the trocar and stilette, the trachea has been transfixed. This is a thing not easily comprehended whilst you study these parts in the dead body, but witnessing the difficulty of doing the operation in the living body, you may conceive it possible. The canula must have within it either a conical piece of wood, or a bougie, which shall pass easily into the slit, and convey in the silver tube; or the tube itself must be cut obliquely at the further end, so as to slip into the perforation; which latter mode is much to be preferred, because the instant it is introduced there will be relief; whereas by using the trocar with the stilette, there is a temporary obstruction of the windpipe. When a tube is introduced into the trachea further down than this, and retained there for some time, the ring above the perforation is pressed inwards, and made convex toward the calibre of the tube, so that there is a permanent straitening of the windpipe at that part; and this, I conceive, will make it difficult, in the event of present success, to withdraw the tube and restore the natural respiration. In the manner of operating which I have suggested, the greater firmness of the cricoid cartilage will prevent this indenting of the upper edge of the perforation. I always hesitate to recommend what I have not actually done, for unexpected circumstances present themselves. I return, therefore, to the consideration of the operation as you have seen it performed. When the membranous space between the thyroid and cricoid cartilages is opened by a crucial incision, upon holding aside the integuments, the patient at once breathes freely. This is of the utmost consequence; it immediately gives him composure; he recovers from the struggle which has perhaps too long continued; and the relief is so perfect that he falls asleep. Now this is so essential a benefit, that we must not resign it without very deep consideration. If, for example, on perforating lower down, the inner membrane should exhibit a degree of irritability at all equal to what you saw in the present instance, you would not be able to give the patient relief—certainly not that immediate relief which is required, and only by cutting out a portion of the cartilage. With regard to the effect of this removal of a portion of the cartilage I speak with some hesitation; but it has occurred in this hospital, when the windpipe has been cut by the suicide, that the cartilages have retracted. An unfortunate girl, determined on destroying herself, put a penknife into the centre of her throat and cut downwards, dividing the rings of the trachea; she lived several weeks, and on

her death the trachea was found very much diminished in its calibre, by the curling in of the cartilages. If we make the incision longitudinally, without taking away a portion of the cartilage, we cannot expect that the patient can have that relief which we have seen given in the present instance, unless we introduce a tube. Holding up the chin and stretching the neck would not tend to open the slit which you have made in the windpipe, but the contrary; whereas you have seen that in perforating above the cricoid cartilage, by holding apart the integuments, and stretching the neck, the patient was remarkably relieved. The snipping away of the angles left by the crucial incision in the membrane, is not so likely to be permanently injurious as taking away a portion of the cartilage, which is essential to the mechanism of the tube, and for preserving the freedom of the passage. The same observation does not apply to the cutting of the cricoid cartilage; but you will remember that it was not my intention to cut through that cartilage; for as it is a continuous ring, and firm at the back part, it would not have opened out: my object was to notch it, and to enlarge the membranous space. It is, perhaps, just as well that the ossification of the cartilage, and the irritability of the membrane within, prevented my accomplishing this, since the recovery has, in all probability, been the more rapid.

REMARKS ON THE *Structure and Formation of the Membranes* OF THE HUMAN OVUM.

By Robert Lee, M.D. F.R.S.*

[With an Engraving on Wood.]

The difficulty of determining the precise period of impregnation, must render all observations on the human ovum before the middle or near the end of the second month more or less vague and uncertain. After this time the organization of the ovum is so far advanced, that the membranous layers which envelop the embryo, and the form of the embryo itself, can be clearly perceived with the naked eye. The amnion is then a transparent sac, which contains the embryo and the fluid in which it floats. The chorion, covered with villosities on the external surface, surrounds the amnion, but is separated from it a short distance by the interposition of a gelatinous fluid, which is deposited in a very delicate reticular texture. There is a third membranous layer, namely, the decidua, which completely surrounds the chorion, and connects the ovum with the inner surface of the uterus. This, as is well known, appertains not properly to the ovum itself, but is a production of the lining membrane of the uterus; for in cases of extra-uterine conception, the chorion and amnion alone envelop the embryo, and a deciduous membrane has been found lining the cavity of the uterus.

In a specimen, however, of Fallopian tube conception, which I assisted in removing from the body of a lady who died about the eighth or ninth week of pregnancy from rupture of the tube and internal hæmorrhage, no organized deciduous membrane lined the inner surface of the uterus, but the whole of it was coated with a thin layer of soft flocculent albumen.

It is to Dr. William Hunter that the merit is due of having first accurately described and represented in his engravings of the gravid uterus, the disposition of the uterine and reflected deciduous membranes. He has described the decidua as a very soft, tender, pulpy membrane, which lines the whole cavity of the fundus uteri, reaching to the beginning of the cervix, and passing a little way within the origin of the Fallopian tubes, at which place it is perforated by small openings. Besides that portion of decidua lining the cavity of the fundus uteri, another portion forms an external covering to that part of the chorion, which is not in contact at the inner surface of the placenta, and which he named decidua reflexa. The ovum lies between a part of the decidua vera, or that lining the inner surface of the uterus, and the decidua reflexa, both of which unite into one membrane at the edge of the placenta; or the decidua vera divides itself at the edge of the placenta into two laminæ, one of which passes between the placenta and the inner surface of the uterus, and the other forms the decidua reflexa, which covers the outer surface of the chorion as the pericardium does the heart.

When the decidua reflexa is beginning to pass over the chorion, there is

* From Medico Chirurgical Transactions, vol. xvii.

at an early period of pregnancy, an angle formed between it and the decidua, which is often extremely thin and perforated with small openings, so as to look like a piece of lace. In proportion as pregnancy advances, the decidua reflexa becomes gradually thinner and thinner, so that at the fourth month it forms an extremely fine layer covering the chorion. It comes at the same time more and more closely in contact with the decidua which lines that part of the uterus to which the placenta is not fixed, till at length they adhere together*.

Dr. Hunter has offered no explanation of the manner in which the decidua reflexa is formed, and Dr. Baillie, who completed his description of the gravid uterus, admits that the manner in which the decidua envelops the ovum has never yet been observed, and therefore can only be a subject of conjecture. The obscurity which has hitherto prevailed on this subject is probably referable in a great measure to the difficulty which has been experienced by anatomists of procuring the gravid uterus for dissection at a sufficiently early period, with the contents undisturbed. The extent of this difficulty will readily be estimated when I state, that the most early case of pregnancy which Dr. Hunter ever had an opportunity of examining in the dead body was of three complete months, and that his description of the contents of the gravid uterus before this period, was drawn entirely from recent ova expelled in abortion.

The greatest diversity of opinion still prevails respecting the structure and mode of formation of the deciduous membranes, though they have been carefully investigated since the time of Dr. Hunter, by many distinguished physiologists. Neither Lobstein, Krummacher, Gardien, Breschet, Dutrochet, nor Velpeau, have been able to discover the openings in the decidua, corresponding with the orifices of the Fallopian tubes, and the last of these authors has concluded from his researches, not only that the decidua invariably forms a shut sac in the uterus before the descent of the ovum, but that it is an inorganic layer, and wholly destitute of blood-vessels during the entire period of gestation. According to this view of the disposition of the parts, it is supposed that as the ovum passes through the Fallopian tube into the uterus, it pushes before it the deciduous membrane lying across the orifice of the tube, and thus acquires the thin membranous covering termed decidua reflexa. "L'ovule, après avoir parcouru la trompe, deprime necessairement la membrane caduque, pour se glisser entre elle et l'uterus, à la surface interne duquel il finit par se coller: dès ce moment, la membrane préexistante se trouve formée de deux portions; l'une, très grande, tapissant tout l'interieur de la matrice, à l'exception du point qui est en contact avec le germe, porte le nom de caduque uterine ou interne; l'autre, très petite, deprimée par la moitié inferieure de la vesicule fecondée qu'elle enveloppe, constitue la caduque reflechie interne, ou l'epichorion. L'etendue de la première augmente en même proportion que celle de l'uterus, et l'agrandissement de la seconde suit, de toute necessité, l'accroissement du germe. Aussi la cavité qui les separe, et qui n'est autre que la cavité deformée de l'ampoule primitive, est elle d'autant plus considerable qu'on s'eloigne moins des premiers temps de la gestation*."

Dr. Burns, who has enjoyed several opportunities of examining the contents of the gravid uterus within a month after conception, has given the same mechanical and erroneous explanation of the formation of the decidua reflexa. "In every case," he observes, "the decidua, consisting of two layers, is completely formed before the ovum descends. Where the embryo passes down through the tube, it is stopped when it reaches the uterus by the inner layer which goes across the aperture of the tube, and thus would be prevented from falling into the cavity of the uterus, even were it quite loose and unattached. By the growth of the embryo, and the enlargement of the membranes, this layer is distended and made to encroach upon the cavity of the uterus, or, more correctly speaking, it grows with the ovum. This distention or growth gradually increases, until at last the whole of the cavity of the uterus is filled up, and the protruded portion of the inner layer of the decidua comes in contact with that portion of the uterus itself which remains attached to the outer layer†."

* An Anatomical Description of the Human Gravid Uterus, by W. Hunter, M.D. pp. 79–83. London, 1794.

* Traité Elementaire des Accouchemens, t. i. p. 232.

† Principles of Midwifery. London, 1820. Page 184.

On the 10th of March, 1832, a young woman who was in the second month of pregnancy poisoned herself with oxalic acid. The uterine organs were removed from the body, without disturbing their contents, by W. B. Hutchinson, Esq. house-surgeon to the St. Marylebone Infirmary, and to his kindness I am indebted for the preparation of the parts now exhibited to the Society, and for the opportunity which has so seldom been enjoyed by anatomists, of dissecting the gravid uterus before the third month of conception. Both Fallopian tubes in this case were pervious, and the ovum being attached by the placenta to the inferior segment of the uterus, it was obvious that it could not have pressed before it the decidua reflexa in the manner usually represented.

Description of the Uterus and appendages of a Young Woman who poisoned herself in the second month of pregnancy.

The uterus had acquired double the size which it usually exhibits in the unimpregnated state. It was five inches long, three and a half in the greatest lateral direction, and two inches in the antero-posterior diameter.

A longitudinal incision was carried down the middle of the posterior surface, crossed by a transverse one parallel to the entry of the Fallopian tubes. The thickness of the parietes of the uterus, though greater than in the quiescent state, were not proportionate to the general increase in the dimensions of the viscus—they were four lines at the fundus, and six lines at the cervix, gradually increasing towards that part; the chief difference was observable in the already enlarged size of the uterine venous sinuses.

The deciduous membrane, which closely adhered to the inner surface of the uterus, was then laid open by two incisions parallel with the longitudinal and transverse incisions previously made in the parietes of the uterus. The cavity of the uterus being exposed, the ovum, about the size of a pullet's egg, came into view, and was observed to be situated towards the lower part of the uterus. The part of the cavity to which it adhered was included between two parallel lines, drawn, the one transversely across the uterus at the distance of half an inch below the entry of the Fallopian tubes, the other at two inches distance from the os tincæ. Consequently the ovum was situated altogether below the entry of the Fallopian tubes, and was unattached both at its upper and lower part, leaving a free space or canal between it and the os tincæ, corresponding to the shape of the elongated cervix, and a much larger cavity between the upper part of the ovum and the fundus uteri. But as this latter space is not only inexplicable on the received theories of the formation of the decidua reflexa, but directly at variance with these, it demands a particular and minute description.

Intervening between the superior and unattached surface of the ovum and fundus uteri, was a broad but shallow cavity, measuring three inches in the lateral and one inch and a half in the antero-posterior diameter, and from one to two lines in depth. The upper concave surface of the cavity, formed by the decidua lining the fundus uteri, or decidua vera, was irregular and slightly reticulated. The inferior convex surface formed by the decidua covering the ovum, or decidua reflexa, was perfectly smooth, resembling the external serous surface of the uterus. Into this cavity the Fallopian tubes freely opened by palpable orifices; that on the left side, by which the ovum had entered the uterus, being rather more than a line in diameter, that in the right rather less. The cavity thus formed between the decidua lining the fundus uteri and the decidua covering the upper and unattached portion of the ovum, was filled with a red-coloured serous fluid.

The ovum was next laid open by an incision through the chorion parallel with the longitudinal incision of the uterus, and the amnion inclosing the embryo was brought into view. The placenta was situated principally over the cervix and posterior part of the body of the uterus, and the decidua closely adhering to the placenta passed across the upper part of the cervix uteri, in the form of a thick reticular membrane. The decidua was then observed to extend upward between the uterus and chorion, every where firmly connecting these together as high as the entrance of the Fallopian tubes. From this point the deciduous membrane was spread out in two different directions, viz. over the upper convex and unattached surface of the ovum, and over the whole concave surface of the fundus uteri, so as to form

the cavity above described, into which the Fallopian tubes freely opened. The deciduous membrane interposed between the ovum and uterus exhibited the usual degree of development and of organization. Where it passed off from the uterus to cover the upper surface of the ovum, it was somewhat thicker than elsewhere, and was divisible into two distinct layers. The tufts of vessels of which the placenta is constituted were more distinct from each other than they subsequently become, and they filled the entire space between the chorion and decidua. The appearance of a division of the placenta into a fœtal and maternal portion did not exist. The different parts of this interesting and most beautiful preparation have been faithfully represented by Mr. Perry, in the accompanying drawing.

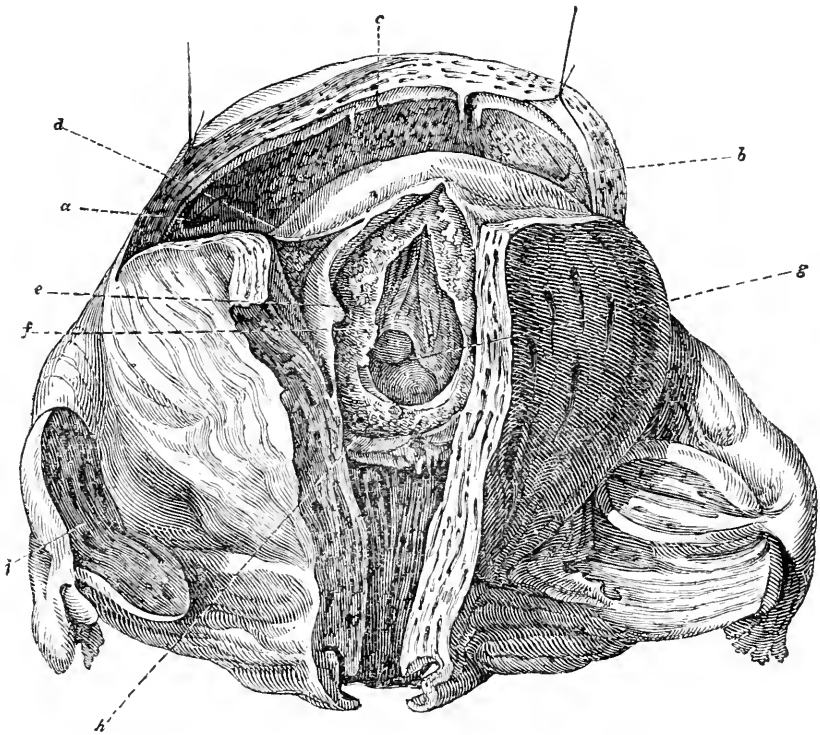
If the statements of the authors above alluded to, and the generally received opinions respecting the formation of the decidua reflexa be well founded, it would follow, that in all cases the ovum would attach itself to the uterus by the placenta, either directly over the edges of the orifice of the Fallopian tube, through which it had descended, or to its immediate vicinity, and that the deciduous membrane would never be found interposed between the uterus and placenta, as it invariably is. The facts which I have now adduced clearly demonstrate, that the Fallopian tubes are open in the early months of gestation; that the ovum may attach itself by the placenta to the fundus body, cervix, or over the os uteri, and that the deciduous membrane forms neither a shut sac nor inorganic layer, prior or subsequent to the arrival of the ovum in the cavity of the uterus. These circumstances are also strictly in accordance with the fact, that when the ovum can first be perceived, it lies loosely imbedded in the soft flocculent albuminous matter which at this period of gestation coats the inner surface of the uterus, and that this pulpy semifluid matter becomes gradually converted into those delicate organized membranous layers, by which the attachment of the ovum to the uterus is so firmly secured during the whole period of pregnancy. The albuminous substance interposed between the uterus and ovum becomes the decidua uteri, or decidua vera, while the albumen which envelops the unattached hemisphere of the ovum becomes the decidua reflexa. To whatever part of the uterus the ovum adheres by the placenta, its relation to the deciduous membranes will be the same, the decidua vera forming the connecting membrane between the ovum and uterus, and the decidua reflexa covering only that part of the chorion which hangs loose within the cavity of the uterus.

From the circumstances now detailed, it also follows that the names decidua uteri and decidua reflexa are improper, in so far as they are founded on speculative ideas regarding the mode in which these membranes are formed, and which, if not positively erroneous, are at least by no means demonstrated. It would be preferable to distinguish these membranes not in this hypothetical manner, but from their anatomical relations, which must be true, whatever be the fate of our conjectures; and I therefore propose to denominate them respectively decidua uteri and decidua ovuli, or uterine and ovuline decidua*.

At the end of the fourth month of gestation, when the ovum has enlarged so as to fill the entire cavity of the uterus, the decidua uteri and the decidua ovuli coalesce, and during the remainder of pregnancy form a thin, soft, pulpy membrane, which is closely united to the inner surface of the uterus, by numerous small tortuous blood-vessels and flocculent fibres. At this period also the villosities of the chorion have disappeared, where the placenta does not exist, and the amnion, the chorion, and the decidua, have become so firmly adherent to one another, that they constitute a membranous sac consisting actually but of one layer, though susceptible of being artificially divided into three distinct laminæ. M. Velpeau asserts, that the decidua uteri, and decidua ovuli, remain distinct membranes until the end of pregnancy; but in seven gravid uteri near the full period, which I have examined, I have never perceived more than three concentric layers in any part of the fœtal membranes. The existence of numerous blood-vessels, proceeding from the lining membrane of the uterus to the decidua, which has also been denied by the same writer, is clearly demonstrated by the preparations of the gravid uterus in the Royal College of Surgeons in London; and it scarcely admits of a

* The term ovuline decidua I have adopted at the suggestion of my ingenious friend, Mr. Owen.

doubt, that these vessels serve not merely to supply nourishment to the membranes which envelop the fœtus, but that they enable the amnion to secrete the fluid contained within its cavity. The numerous small arteries which proceed from the inner surface of the uterus to the decidua covering the placenta, are also, I conceive, solely destined to perform the function of supplying this organ with nourishment, and not, as has generally been supposed, to effect certain changes in the fœtal blood as it circulates in the vessels of the placenta.



Explanation of the Woodcut.

a, The right Fallopian tube, pervious.
b, The left, ditto.
c, The decidua uteri, or decidua vera.
d, The decidua ovuli, or decidua reflexa, covering the unattached part of the ovum.
e, The decidua uteri, passing down between the ovum and uterus.
f, The chorion.
g, The amnion.
h, The placenta, lying between the chorion and decidua, crossing the cervix uteri.

VENEREAL CASE TREATED WITH FUMIGATIONS.

To the Editor of the Medical Gazette.

SIR,

IN the autumn of 1831, Capt. T. contracted syphilis, which shewed itself by a chancre, occupying two-thirds of the prepuce, for which he took internally and rubbed in mercury, and apparently got well. About five months after this his general health became much deranged, and innumerable blotches appeared on all the surface of the body and limbs; for these, and on account of his ill state of health, he was advised to leave Ireland, and proceed to Harrowgate, for the benefit of the baths at that place, and other appropriate treatment.

He had scarcely commenced the former, when the blotches became open ulcerations, from the size of a common playing card to that of a sixpence. The irritability became excessive, and his health daily worse; he, notwithstanding, persevered in the treatment advised for eleven weeks, but only with progressive aggravation of all the symptoms. His physician then recommended his making the best of his way to London, and to take the sulphurous fumigations under my direction.

On his arrival, I found he had an ulcer in the throat; fœtid discharge from one ear; his forehead, nose, and cheeks, were covered with a continuous scab, with extended surface of coppery coloured redness round it and the other ulcerations; he had fœtid discharge from the nostrils, and snuffling speech, indicative of caries or disease of the nasal possages; nodes on each tibia, the pains of which occasioned his nights to be sleepless; and the original chancre was open to its former extent. He was in a very weak state, and the case seemed formidable; he, however, commenced the sulphurous fumigations on the 26th of September, taking one daily. His improvement, even under this simple mode of treatment, was rapid. In the short space of a week, more than one hundred of the ulcerations had healed, his throat was better, and his general health seemed improved; but his night pains he stated to be increased. It should be borne in mind that, until this time, no internal medicinal treatment was resorted to; he solely took the sulphurous fumigations as directed by his physician, a gentleman who had in his own person experienced the advantages of them. Although the amendment thus far was so manifest, yet the leading characteristics of the case being considered, his physician being absent, and from my knowledge of the sulphurous fumigations, I dare not calculate on the progressive improvement of the patient, nor on the permanency of the benefit which he had already received, without the conjoint aid of mercury; I therefore felt it my duty to urge his taking further advice. He consulted Mr. Brodie, who was of opinion that mercury was necessary to establish a cure; and, there being no continuous surface free from ulcers, on which the ointment could be rubbed, he was ordered fifteen grains of blue pill every 24 hours, with sarsaparilla, and to continue the fumigations. He commenced the mercury on the 6th of October. On the 9th he was under the influence of the medicine, which was diminished to 10 grains. On the 10th it was further diminished to 5 grains in the 24 hours. On the 12th it was needful to discontinue the medicine altogether; he, however, went on with the sarsaparilla and the fumigations. The progress will perhaps be best considered by reference to the following note, which I had occasion to write to Mr. Brodie.

"Sir, I hope the case of Capt. T. will be satisfactory to you, and tend to prove the utility of the fumigations, which rendered very few of the blue pills necessary before he became duly influenced by the medicine. Every ulceration has healed; the pains in the shins have quite left him; the nodes are gone; and I think you will immediately perceive how much the coppery coloured redness has left the face, and is disappearing from all the healed patches on the surface of the body and limbs."

Dated Oct. 17, 1832.

From the date of this note, the patient's recovery proceeded with the same celerity as from the first of the treatment. He has left London, perfectly convalescent, and continues to take only the sarsaparilla. In all, he took but 34 fumigations between the 26th of Sept. and the 6th of the present month, and latterly only one every other day. This was the whole of the treatment that was resorted to, with the exception of one dose of castor oil, which was directed with a view of abating ptyalism. It may be said from the speedy recovery of this gentleman, that there was a favourable idiosyncrasy of the system, which disposed him to be so readily influenced by the treatment. It might be so; but such a conclusion, I think, should not be hastily assumed; for I have had similar cases, treated with similar success, and there has been no relapse though years have gone by; and I can now refer either to the patients themselves, or to the medical gentlemen whose patients they were. But confining myself to the case above stated, I would observe, it was one of those which at first sight, under the customary modes of treatment, would lead every medical practitioner to conclude that he should

have a rebellious, or perhaps an incurable disease, to contend with.

I think the success attending this and similar cases is mainly attributable to the *heat* by which the patient is surrounded when submitted to the process of fumigation; its advantages when we wish to mercurialize the system have long been acknowledged. I have often had to observe too the beneficial influence of the sulphurous fumigations, not only in venereal, but in other obstinate ulcerations. The stimulus of the sulphurous acid gas certainly agrees well with them, and disposes them to heal, as instanced in the above case, before the conjoint aid of mercury was resorted to; yet I cannot conceive that sulphurous fumigations would alone have done permanent good in such a case, without the aid of mercury. It is the combination of the two remedies, constituting in this country almost a new mode of treatment, which I think deserves the attention of the profession.

I feel, however, that I must conclude these remarks, concise as they are, on account of the value of your pages; otherwise, from a conviction arising from eleven years practical and exclusive experience with the results of the fumigatory method of treatment in various diseases, I believe that such observations, if more ably advocated, would embrace matter of valuable information in general, and of which many of the profession have only a very indefinite knowledge.

I am, sir,
Your most obedient servant,
JONATHAN GREEN.

40, Great Marlborough-street,
Nov. 20, 1832.

STATE OF THE TONGUE IN DISEASE.

To the Editor of the Medical Gazette.

SIR,

I HAVE often thought that the state and colour of the tongue in disease unduly influenced the minds of medical men; experience confirms me in the belief. Its situation in the inferior part of the mouth, and composed as it is, of muscular fibres, arteries, veins, nerves, and membranes, which, independent of the sympathy (a word used here in its conventional meaning,) established between it and remote organs, expose it to various changes. Though ready to admit that the supply of nervous energy which it receives from the third branch of the fifth, the hypo-glossal, glosso-pharyngeal, and thin interlacements with the great intercostal and par vagum, must influence its sympathetic appearances in diseases of the thoracic and abdominal organs, yet there are cases where these appearances have no physiological or pathological relation to the diseased viscus.

Our admiration of the great men who have preceded us in the paths of medical inquiry has, doubtless, often led us into erroneous conclusions, where, in our investigations of morbid or healthy structure, instead of following nature as our unerring guide, we set out with certain data which the writings of those men supply, and are content if we can only verify their descriptions. Had the genius of Bichat been content with the vague notions which Haller left us of the membranes, in which he could discover nothing but the modification of cellular membrane, his best claim to immortality would have been lost.

The tongue, which is covered by a mucous membrane constantly moistened with a fluid, secreted either by the imaginary glands of Bichat, the salivary glands of Piorry, or, according to Majendie, by the entire surface of that membrane, has, since the first records of medicine, been considered as an index of the healthy or diseased state of the stomach and intestines. That it does often indicate the condition of these organs, is certain; and perhaps one of the most accurate observations of Hippocrates is, that aphthæ on the tongue of adults, without any specific disease, indicate the scanty, capricious, and irregular action of the lower intestines; but that there are many cases where there does not appear the slightest sympathy between it and the diseased viscus, is equally certain. We often find ulcers in the mucous membrane of the stomach without any corresponding symptom on the tongue. The mucous membrane which lines the mouth being a continuation of that which covers the tongue, we might, *à priori*, suppose that its functions should be similar; but observation proves this not to be the case. This membrane, though similar in organization, differs

essentially in function, according to the organ it supplies: the pituitary differs from that of the stomach and intestines; in some animals the splenic and pyloric portions of the mucous membrane of the stomach differ; whilst, in the class ruminantiæ, the mucous membrane of each stomach differs in function from the other. The secretion of the mucous membrane of the tongue, which, like other mucous membranes, has been considered as an outlet for the effete matter of our bodies, is increased both by the nervous energy with which it is supplied, and the constant action of the tongue, by which the dilatation and contraction of that membrane is augmented.

Most writers on symptomatology are tediously minute on the importance of its appearances in disease; but many of the morbid hues which they make it assume, appear to me distinctions without a difference. Landre Beauvais says, if there be great dryness of the tongue in acute diseases, internal inflammation is to be feared; but then he says, that if the patient breathe with the mouth open, no inference can be drawn from it. Roughness of the tongue, which, he says, is caused either by weak or violent excitation of the absorbent vessels, or spasm, frequently indicates delirium; again, he says a villous tongue *may* indicate chronic weakness of the abdominal viscera, or inflammation of the lungs, and may announce the approach of hydro-thorax. What other anomalous diseases can such a tongue indicate? I shall not dwell upon the endless variety of shade, which the author of the Doctrine Physiologique insists on, confident that the less we suffer ourselves, in our diagnosis or prognosis, to be guided *solely* by them, the less cause we shall have to regret it. The same may be said of the coats of the tongue. We often see people in the enjoyment of good health, whose tongue is constantly loaded; and in France I find that several experiments have been made on the effects of abstinence on the tongue, which always appeared loaded as in disease, but which a little food soon cleaned. The mucus of the tongue being more abundant than that of the rest of the mouth, and placed, as the tongue is, in a never ceasing current of air (when the mouth is open) passing and repassing to the lungs, its aqueous portion must be incessantly evaporating, whilst its grosser matter becomes incrusted on the superior surface of the tongue, which its quiescent state in disease greatly assists. The rapid and hurried respiration which unavoidably ensues when diseases of the abdominal organs check the descent of the diaphragm, thereby diminishing the expansion of the lungs, must increase this dryness. How far the tongue may enable us to ascertain the nature of disease, and whether the serous parenchymatous, or mucous texture, be its seat, is a refinement at which I have not yet arrived. But when we find such men as Percival and Graves, of Dublin, disregarding, in a great degree, the appearances of the tongue in the management of disease, our faith in the paramount importance of the tongue, unless it be like fatanic faith wedded to some clear falsehood, must begin to yield.

I shall close this letter with a short extract from Dr. Graves on Fever:—"As to the tongue at an advanced period of fever, I have often derived the greatest advantage from wine and opium, although the tongue was dry, the colour of old mahogany, or else coated with yellowish-brown dry fur, and protruded with difficulty, while the teeth and gums were covered with sordes. Wine or porter, in moderate quantities, seem generally to agree better with this tongue than opium: in some cases, however, the latter is advisable."—I am, sir,

Your humble servant,
RICHARD BURKE, M.D.

4, Bolton Row, May Fair,
Nov. 7, 1832.

CASE OF EMPYEMA—PARACENTESIS—RECOVERY.

By W. G. GOWING, M.R.C.S.
Surgeon, of Norwich.

MR. RICHARDSON, æt. 22, a healthy active man, of fair complexion, by trade a baker, was, in March 1830, attacked with the following symptoms. An obtuse pain in the chest, difficulty of breathing, attended by painful inspirations, cough, quick pulse, dryness of skin, white tongue, great thirst, urine scanty and high-coloured. These symp-

toms soon yielded to the use of the lancet; sixteen ounces of blood were taken from the arm, a blister applied to the chest, and a purging mixture, composed of salts and senna, given every four hours till the bowels were freely evacuated. In about three weeks he was again able to resume his business, but did not entirely lose the cough. He occasionally complained of shortness of breath, with flying pains about the chest, till April 11, 1832, when the cough returned with increased violence; he soon began to lose flesh; his countenance became pale; his breathing more or less hurried by bodily exertion; pulse varying from 130 to 140 in a minute; urine high coloured; tongue clean and red. The fever which came on towards evening was generally preceded by rigors, and terminated by profuse perspiration. The expectoration at first appeared viscid and opaque, but soon assumed the character of purulent matter: from five to six ounces were discharged daily, for three months prior to the operation; his nights were passed almost entirely without sleep. The tartar emetic ointment was rubbed on the chest, five grains of ext. Papaveris given every night, and the decoct. Lichen. with mineral acid, three times a-day. His diet consisted chiefly of milk and animal broths. In consequence of not being able to lie on the right side, I was induced to examine the chest: the left side was evidently larger than the right, more particularly on the posterior surface. On placing my hand on the swelling, and desiring my patient to cough, I was fully convinced of the existence of a large quantity of fluid. I therefore felt no hesitation at once in recommending an operation, which my friend, Dr. Lubbock, fully concurred in, as the only chance of preventing immediate suffocation. On the 27th of July the operation was performed, in the following manner. The patient being placed on a chair, with his shoulders slightly elevated, the integuments were drawn up with the left hand; an incision was made between the second and third spurious rib on the posterior part of the chest with a lancet, through which a silver canula was passed, and upwards of eight pounds weight of matter evacuated. The canula was then withdrawn, and a compress of lint applied. Almost immediately after the operation the cough ceased, as also the expectoration.

28th.—Much relieved by the operation; passed a good night; pulse 110.

29th.—Passed rather a restless night; is free from pain and cough; a considerable quantity of matter discharged from the wound.

A pill containing five grains of Ext. Papav. and five grains of Pil. Hydrag. to be taken at bed-time. Took freely of milk broth.

August 3d.—He is improved in every respect. Pulse 100; appetite good; ate some animal food, and drank half a pint of porter.

Two grains of Sulphate of Quinine, three times a-day.

12th.—He gains strength daily, takes gentle exercise, and enjoys his food.

Sept. 10th.—Since last date he has improved in health and strength, being capable of sustaining considerable bodily exertion without much fatigue.

October 4th.—All appearances of pectoral disease gone, wound healed, and his strength completely restored.

From the history of this case, it appears reasonable to infer, if my patient had been left entirely to nature, he would inevitably have lost his life, and that the cure may very fairly be ascribed to the operation.

Norwich, November 8th.

MEDICAL GAZETTE.

Saturday, December 1, 1832.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."
CICERO.

CLOGS OF THE ANATOMY ACT.

THERE never yet was a measure of any public import adopted, that there was not a host of dissatisfied cavillers raised to attack it. What grumblings, what abusive railings, and Billingsgate rhetoric, have we not heard poured out, in certain low quarters, against the act for regulating the schools of anatomy!

The resurrection-men themselves could not apparently take a warmer interest in denouncing it: no doubt its existence as a law is a dreadful grievance to the friends, followers, and survivors of Bishop; their occupation is gone—they must turn their hand to something else; but before they do so, we must not be surprised to find them uttering volleys of curses on what they consider to be the hardship of their situation. They curse the friends of order, they revile the legislature; above all, they abuse the Act. This, however, is just as it might be expected: for our part, we have no whit the worse opinion of the Anatomy Act for all their abuse.

Forsooth, it does not work well: there has not been a competent supply of bodies in the schools since the beginning of the season—the first season of its operation. This puts us in mind of the extravagant expectations of certain people regarding another bill—which was to give them meat, drink, and clothing, almost without asking for either: but, alas, they have only been disappointed! Will such persons never have common sense, moderation, patience? A state of things of the most odious description has been got rid of; a band of desperadoes, the terror of the public, the detested, though necessary, agents of the anatomical teachers, have been dismissed; and a new order prevails. The machinery is stiff as it sets to work in the commencement; the discontented pick flaws in it, and the impatient are up in arms because it is not perfection itself.

We never had any idea of maintaining that the Bill—still less the Act—even approached perfection: we took it, and made up our minds to be content with it, seeing that it was probably as good as could be hoped for from the public and the legislature, in this boasted time of enlightenment. It was our impression, after duly considering the state of public feeling, that we ought to make the best bargain we could, and not stand higgling for comparative trifles; and having obtained the Act, either as a boon or as a right—for we do not care to consider which—we thought, and continue to think, that the measure should be allowed a fair trial: the question should be, not how does it work, but rather, has it got time to work? Such as it is, we should conceive it but prudent not to encumber and clog its operations by superfluous or unneeded assistance. Plan after plan is suggested to improve or guide the machinery: we should recommend great caution in adopting any; or at all events, any proposition that should be adopted ought to be clear and explicit, and beyond a suspicion of being engendered for a partial purpose.

There has been indeed only one plan proposed which we deem deserving of notice—that for securing an equitable distribution of the subjects obtained from the parishes. It was discussed at two meetings of the principal metropolitan teachers of anatomy; it was adopted by a decided majority; but we find, after all, that it is not to be acted upon. This may seem strange, but it is not without some shew of reason: it results from the present supply from the parishes being limited, and the principle which seems to actuate the non-contents is, that where there is scarcity and dread of a famine, it is better that a few should be well provisioned than that all should starve.

In truth, here is the hitch in the old place: it is not the profession that is wanting to the public, but the public to the profession. The legislature has done its part—the public have but partially done theirs.

Several of the parishes have handsomely come forward, and liberally supported the views of the legislature; but a large number, we regret to say,

have refused to give up their unclaimed dead—or rather, they take care to leave none unclaimed.

But whence is this refusal?—are we sure that it emanates from the collective sense of the parishes, or from the individual wisdom of the overseers? Are the public (or that portion of it included in those latter parishes) really chargeable with this embargo on science, or is it the doings of their functionaries? That these persons are immediately the obstructors of the supply, we know; how far they act by authority, we are not sure: but we would fain believe it a libel on the public name to attribute the obstruction to that source.

After so many years of well-contested argument, with the ultimate surrender of opinion, if not conversion, of the great unprofessional mass of the community, are we now to have a recusant opposition imputed to them, in consequence of the inveterate prejudices of a few? The charge clearly comes home to those personages who hold the office of overseers, and who should bethink themselves well what they do when they proceed to interpose their brief authority between the public good and their own self-importance: they should see that their zeal may not overstep their discretion. We say not this in any spirit of unkindness; we are willing to make due allowance for the example displayed by certain agitators of the medical press—mischievous blockheads who know not, nor ever care, what the result of their doings may be, so they succeed in setting the pupil against the teacher, and the public against the whole profession.

There is another source too of ill example—though it may be but a consequence of the last. We have heard, and upon authority which we cannot question, that the parish officers have misleaders nearer home. There are *parish surgeons* who have a voice influential in the disposal of the dead, who, however, not only will not employ that voice in the cause of the promotion of science, but absolutely discountenance, both by word and deed, the advancement of that cause. This to us, we must confess, is one of the most unaccountable sources of opposition—at the same time that it is, we fear, one of the most effectual. What can the lay officers think of the propriety of giving up bodies to the schools, when they find their professional brother functionaries totally opposed to it? Must they not naturally assume that there is something revolting in the process of dissection; or that, at least, the office of the anatomist is one of questionable utility? That there can be any regularly-educated surgeon who would give currency, by the sanction of his example, to such absurd opinions, is what we can scarcely believe; yet that this is the tendency of the course pursued by those professional men in authority of whom we speak, is undeniable. Their motives for such conduct can only be inferred to be invidious, partial, prejudiced, or selfish. We blush that such inferences should be drawn regarding men of the profession!

It is with much reluctance that we have taken up our pen at all at the present moment, to treat of the Anatomy Act—an act which, we are persuaded, were it let alone by those "cogging, cozening slaves," whose cue is to abuse and revile it, would work peaceably and usefully—would want but little more than patience and a fair trial to put its machinery into play—and, above all, would conciliate the good opinion of the public at large by the simplicity of its operations. But the mischief, we fear, is done, and will require a remedy or reaction; the Act alone will probably now be insufficient for the full attainment of the object at which it aimed; and it may be neces-

sary at least to devise some means by which such supply of bodies as can be procured may be made available to the purposes of all the established schools. The plan of equitable distribution, proposed we understand by Mr. Grainger, cannot be abandoned with any good reason or good grace; and though it should at first apparently bear somewhat hard on those teachers who are sure of a supply, it would at the same time relieve them from the charge of an undue monopoly, and undoubtedly soon remove a most prejudicial impression from the public mind; for nothing can have a more injurious effect, in the eyes of the public, than variance and disunion among the teachers of anatomy. We do not say that any such variance really exists at present, but it should cautiously be guarded against, lest the public should believe there does. Even a difference of opinion between such parties, and on such a subject, would run the chance of being magnified into a struggle, which would excite no sentiments but those of ridicule and disgust.

We believe it to be a fact which cannot be disputed, that there is ample *materiel* for an abundant supply of the schools, if but the parishes generally, and the parish officers in particular, would contribute that assistance which was all along expected from them. It was matter of calculation, before the passing of the act—nay, long before the bill was drawn up—that there would be ample resources, independent of exhumation, when once a fair legitimate measure should be adopted. The calculators were right, so far as the amount of the resources was concerned; but they neglected an important point—to determine how they should be made available, and how the intrigues and mischievous interference of individual disturbers should be prevented. To the latter source do we primarily attribute the recent inconveniences which have been complained of; we are convinced that medical agitation has far more to do with the matter than any thing essentially incorrect in the principle of the Act, or any illiberal feeling on the part of the public.

CHEAP SUBSTITUTE FOR QUININE.

The extreme dearness of this article—the well-known remedy for the cure of ague—and perhaps the only infallible specific that medicine affords, has set many inquirers to work, in order to discover some substitute of equal virtue, but within the means of the poorer classes affected with intermittents. M. Magendie, who was entrusted by the Academy of Sciences with the task of performing a series of experiments for the purpose of ascertaining the virtues of the powder of the leaves of holly (*ilex aquifolium*), has just returned a very favourable report. He tried it largely in numerous cases of ague committed to his charge in the Hôtel Dieu; and in consequence of his report, the gold medal of the Academy, value 1500 fr., has been awarded to M. Rousseau, the discoverer, "for having added to the materia medica an indigenous remedy, which will be found to be of the greatest value wherever agues are endemic and the natives poor."

NOTE FROM DR. ELLIOTSON.

In our article on the Medical Schools and Dr. Elliotson, published a fortnight ago, after adverting to the unusual modes adopted by that gentleman of carrying on the discussion, we added:—"Under such circumstances, it is in vain to look for any thing like a cool and dispassionate investigation of the points at issue; the learned Professor will therefore excuse us for requesting, that if he has aught farther to adduce, he may confine himself to the new channels he has opened for communicating with the public—for here, as regards this journal, the controversy must end." Notwithstanding this intimation of our intentions, we have received a note from Dr. Elliotson, enclosing a letter from the Secretary of the London University, which the Doctor *desires* us in peremptory

terms to insert. We shall not do so. We beg, however, to observe, that had the request been made with common courtesy, we should have complied with it: as it is, we feel bound in candour to give the purport of Mr. Coates's letter, which is this,—that no proposal has been either adopted or formally made to any of the "Faculties" in the London University, that the Introductory Addresses should be laid before them previous to delivery. From this we infer, that the "determination" (the word we used) of the other Professors to avoid hereafter the repetition of certain indiscretions to which they are sensibly alive, has not been expressed by them *quasi* the "Faculty of Medicine," and consequently is not recorded in the Secretary's books. So far, and no farther, does this communication extend; and we are perfectly willing to give Dr. Elliotson the full benefit of our mistake as to a formality, and that too regarding a point perfectly extraneous from the subject of the discussion. Had he attempted to disprove our arguments regarding the schools, or to explain away the proofs afforded by his own letters of acknowledgment and thanks, that his charge of unhandsome conduct regarding the publication of his lectures was unfounded, we might possibly have been compelled, however reluctantly, to enter upon the subject again; but when we declare that no attempt whatever of this kind is made, we trust our motives for declining to do so will be appreciated. In truth, we fear to trust ourselves, lest, under the provocation of repeated incivilities, we should violate that temper and forbearance which respect for our readers and ourselves alike prompts us to preserve.

MEDICO-CHIRURGICAL SOCIETY.

November 27, 1832.

W. LAWRENCE, ESQ. IN THE CHAIR.

Fatty Discharges from the Bowels and Bladder.

Two interesting papers were read this evening, which served to throw still further light on the subject with which Dr. Bright opened the business of the session: the discharge of fatty matter from the intestines. The paper of Dr. Elliotson, *on the Discharge of Fatty Substances from the Alimentary Canal and Bladder*, gave an account of most of the old cases on record which had any connexion with the subject. He began by a notice of the ambergris found in the rectum of the spermaceti whale, which, he said, was seldom observed higher up than seven or eight feet above the anus, and one mass of the substance had been obtained which weighed above 180lbs. A variety of old authorities were quoted, to shew that instances of similar formations were by no means rare in the human subject. Tulpius gives a very exact account of a female who, for above fourteen months, went on daily discharging from the bowels a large quantity of a yellow fat: it used to settle over the fæces like melted butter. It was remarkable, that, in this case, there was no pain in passing the stools — no wasting of the flesh, or colliquative fever; but there must have been, says the author, some internal heat, sufficient to dissolve the fat and keep it fluid—"latitante in ventre ipsius occulto aliquo calore dissolvente proculdubio quem hic describimus adipem." Appearances of a similar kind have often been observed in the discharges of individuals who have taken castor-oil. Dr. Elliotson met with two cases, in the course of his practice, in which fatty discharges were strikingly present; and he had obtained an account of a third case, with notes of the post-mortem examination. The first person whom he had to treat in the disorder, was a patient who was under his care for phthisis and diabetes. The discharges of fluid fat were very abundant, and alternated with the presence of bile in the evacuations. The patient sunk exhausted. There was another case — that of a female—which was strongly analogous; and in the third, of which Dr. Elliotson had obtained an account, the patient was an old lady, who died wasted in a very extraordinary manner. It reminded Dr. E. of the case in Tulpius which immediately followed the one already quoted; where an old woman voided large quantities of fat from the bowels and bladder, and towards the termination of the disease, which proved fatal, was affected with fever, which wasted her to such an extent that she became a parched and juiceless corpse. Dr. Elliotson referred to a valuable letter of Dr. Babington to Sir Everard Home, given in the Philosophical Transactions for 1813; and stated the substance of a note which he had himself received from Dr. Prout, relating to fatty discharges from the bladder. Dr. Prout observed, that such appearances in the urine had sometimes attracted his notice; that he did not consider the fatty substance in such cases to be of the nature of cholesterine, but rather of margaritic acid; and he added, that he generally looked upon cases of this description as

connected with malignant disease of the kidney, or some other important organ.

In a short conversation which followed, Mr. Stanley alluded to the researches of Mr. Brodie, concerning the office of the bile, and the more recent and ample lucubrations of Tiedemann and Gmelin, touching the same subject: the latter authors hold that the bile acts upon the fat in the intestines, in order to render the chyle perfect. Mr. S. thought that the facts stated by these physiologists might elucidate, in some measure, the alternate appearances of bile and fat in the cases read during the evening.

[We purposely defer giving an account of Mr. Lloyd's paper this week, hoping to have more room for it in a future number.]

ST. THOMAS'S HOSPITAL.

Injury of the Hip-joint, and Secondary Luxation into the Ischiatic Notch.

(Communicated by F. Ward, Surgeon, &c. Balham Hill, Surrey.)

The following interesting and rare case is at present in Henry's ward, under the care of Mr. Travers.

Michael Flemming, æt. 40, a tall but not very muscular man, a shoemaker, was admitted September 27, having received an injury to the hip-joint from a fall. On admission he stated, that while walking on the pavement a month before, he slipped from the curb-stone, and fell with the whole weight of his body on the left hip, which part, he thinks, struck against the edge of the stone. On attempting to rise he again fell, and struck his knee. He was taken to Guy's Hospital and examined, but neither fracture nor dislocation being made out, he was dismissed. On the following morning he was brought to St. Thomas's Hospital. No fracture nor dislocation could be detected; he complained of a good deal of pain in and about the hip-joint, for which he was cupped freely and dismissed. After this he obtained admission into St. George's Workhouse as a pauper, where he was again carefully examined by the parish surgeon, but with the same result. He remained here a month, suffering very severe pain at times; kept his bed, and had the parts fomented frequently. He also states, that the day after the accident he could perceive that the left leg was a little shorter than the right; he could, however, bring the foot to rest on the ground when in the erect posture, by holding any thing to support him, though he could not bear the weight of his body on that leg, nor advance it before the other. He continued to suffer pain in the hip all the time he was in the workhouse.

He was seen on the day of admission by Mr. Travers, who examined him standing and lying down. Both legs were of exactly the same length, the left knee a little more advanced than the right; no alteration could be observed in the appearance of the hip-joint, and the contour of the buttocks was uniform. He could not raise the left thigh from the bed without the assistance of his hands; when standing erect he brought the foot and heel to the ground, but could not bear any weight on it, nor advance it before the other; he had a constant pain in the hip, extending down the thigh to the knee.

Directed to remain quiet in bed, and apply a large blister over the hip-joint.

The following week he still complained of pain; the blister was therefore repeated, and with considerable relief.

A third blister was applied to the outer side of the thigh. On Thursday, November 15th, the man's lameness continuing, Mr. Travers again examined the limb, and was much surprised by the following appearances. The injured thigh was found more than an inch shorter than the other; the knee raised and inverted; the foot also turned in; the great trochanter forming a remarkable prominence on the outer and back part of the gluteal region. Rotation outwards caused considerable pain, and the head of the bone could be distinctly felt to strike against the part on which it rested. The thigh could be carried backwards and outwards to some extent, but not inwards or forwards.

The nature of the injury, as it now existed, was very evident; and although a period exceeding three months from the time of the accident had elapsed, Mr. T. determined to attempt the reduction. He was therefore taken into the operating theatre, and placed on a table on his right side, a padded girth passed so as to fix the pelvis, which was then made secure by a cord to a fixed point; a linen roller applied round the thigh, and the padded strap buckled round above the knee, to which the pullies were attached. Extension was then made across the lower part of the right thigh for twenty minutes, without any change being produced. A vein in the arm was opened, and thirty ounces of blood taken. The extension was kept up, and doses of tartarized antimony administered for a considerable time; but neither sickness nor syncope induced. During the extension the leg was rotated, and an assistant endeavoured to raise the bone by means of a round towel passed over his shoulders and under the upper part of the patient's thigh. This process was continued for near an hour. By passing the fingers from the trochanter along the neck of the bone, the round head could be partially felt, deeply and firmly fixed in its position.

All means having failed to replace the bone, he was removed to bed, for nature to complete that which no doubt she had already commenced—namely, the formation of a new acetabulum.

Observations on the preceding Case,
By Mr. Travers.

The above case is accurately stated by my friend and former dresser, Mr. Ward, who was with me at the first and subsequent examinations. I can explain it only by supposing one of two primary accidents. 1. The laceration of the teres and capsular ligaments. 2. The comminuted fracture of the acetabulum on its ileo-ischiatic side.

I know that a dislocation may, from hurry or insufficient care, be overlooked or mistaken; but this was not that case, as will be concluded from the facts stated in the narrative. Secondary luxations arise from such casualties as those above-mentioned, and also from destruction of the parts forming the articulation, by the inflammatory, *i. e.* ulcerative process. The last is so marked and so slow a process as to be inadmissible in the present case as a mode of explanation. Its frequency makes surgeons sufficiently familiar with it. Unreduced luxations are generally viewed as opprobrious to the surgeons who have been called to them; but a case like the preceding would be very uncharitably, or rather unjustly, made the subject of a reproachful comment. It is on this account that its publication is important, and that I avail myself of the opportunity of adding a remark or two.

At the end of a month from the accident, I undertake to say positively that no recognizable luxation existed; yet there was lameness and pain in the joint and its extended motions, which led me to suppose it the seat of ligamentous inflammation from the concussion, and to blister it freely. The signs of synovial inflammation, or "morbus coxæ" in its first stage, were not present, and the health was not disturbed. It is now a dislocation so palpable as not to admit of a doubt; and the question is, how and when the bone became luxated in the interval between the end of September and the 15th of November. If the preliminaries to dislocation (as the tearing through of ligaments, or a breach of the wall of the acetabulum) had taken place at the moment of the injury, the head of the femur might afterwards be so easily displaced as that its actual escape might be unperceived.

The ulceration of the lacerated capsule, the separation, or perhaps extraneous attachment, of an insulated fragment of the wall of the acetabulum, might either of them be accomplished in this interval without any general or diffused inflammation of the joint.

Subluxations take place, in the shoulder and hip-joints, from injury as well as from disease. Their signs are necessarily, like the displacement, partial and imperfect. As the process of absorption advances, the head of the bone gradually passes on, and then over the border of the receiving cavity, and imperceptibly the semiluxation becomes total. In the ginglymoid joints—*e. g.* knee and elbow—though the semiluxation is yet more frequent, the injury seldom proceeds the length of complete displacement, owing to the different disposition of the articular surfaces as compared with the ball and socket-joints.

Two circumstances noticed in this case serve to confirm the belief that the injury of the ligamentous or bony structure predisposed to the luxation. 1st. The unremitting pain from the time of the accident, and its material relief by the repetition of blisters. 2d. The notorious shortening, disfiguration, and increased lameness observed at the end of seven weeks from the patient's admission; which led to the discovery of the complete dislocation.

Bruton Street, Nov. 25, 1832.

ST. GEORGE'S HOSPITAL.

Case of Amputation at the Shoulder-joint, with some Observations by Mr. Brodie.

James Spawforth, æt. 19, admitted July 11, 1832, under the care of Mr. Brodie.

Nov. 21st.—This patient has at present several sinuses (seven or eight) in the neighbourhood of the left shoulder-joint, from which is discharged a thin, puriform, offensive fluid. Two or three of these openings are seen on the skin covering the upper and back part of the scapula, leading down to the supra spinal fossa and spine of the bone; others at the anterior and posterior edges, and one at the outer and lower part of the deltoid muscle. From the former of these, dead or diseased bone can be distinctly felt, when examined by means of a probe; from the latter this is by no means distinct. The muscles about the joint, and of the upper extremity, are wasted, but the integuments ap-

parently not much affected by the disease. Any motion of the joint produces excessive pain, especially when accidentally shaken or jarred. He suffers little when at rest, but sleeps indifferently; he has no cough, palpitation, or other symptom of visceral disease. Pulse generally about 96; bowels regular; urine natural; appetite good.

His aspect is sallow and exsanguine, but this would appear to be natural.

About two years and a half ago, while living in the country, he struck his shoulder against the handle of a truck. No swelling, and but slight pain, succeeded the accident; the latter however continued, and in three months he was unable to move the joint freely, partial anchylosis having supervened. He came to London, and placed himself under the care of Dr. Gordon and Mr. Guthrie. Leeches, blisters, caustic issues, and rest, were recommended; and under this treatment he was considerably relieved. He returned into the country, and remained free from pain, but with slight anchylosis of the joint. Some person in Liverpool advised that forcible means should be adopted for the removal of the stiffness; and about ten months since this was had recourse to, upon which inflammation and abscess supervened: the latter presented itself at the fore part of the pectoral and deltoid muscles, was punctured, and a large quantity of pus escaped. Since that period abscesses have continued to form and burst, producing the sinuses above described. He laboured about four or five months since under a severe attack of bronchitis; and although a young man, has always lived a very irregular life. Since his admission into the hospital he has taken sarsaparilla, nitric acid, quinine, &c. with a view to the improvement of his general health.

22d.—Several consultations having been held on this case, and the patient constantly expressing a wish that the part should be removed, it was agreed that the arm should be amputated at the shoulder-joint, and that the diseased bone should if possible be extracted.

At one o'clock P.M. the patient was taken into the theatre and seated on a chair. A round towel was placed across the lower part of the chest and held by an assistant, to prevent the patient moving from the seat. Mr. Cæsar Hawkins made pressure on the subclavian artery in the neck, which was found to command the pulse. Mr. Brodie proceeded to the operation.

Operation.—An incision, commencing at the sinuses on the back of the shoulder-joint over the outer portion of the spine of the scapula, was carried forwards, outwards, and downwards, to within an inch or an inch and a half of the insertion of the deltoid muscle; from thence it was continued upwards and inwards, towards the coracoid process of the scapula: the parts were now dissected up from the bone, forming a flap of the deltoid muscle. The operation was so far effected by means of a large scalpel. Several vessels were divided, but of small size.

A common amputating knife was now employed, which was carried below the acromion process, directly into the cavity of the joint. [The patient now struggled most violently, so much so that the assistants could with difficulty retain him on the chair.] The arm from the elbow was now pressed towards the side so as to evert the head of the bone, and with one incision the parts beneath were divided downwards and outwards, forming another flap, somewhat corresponding in shape with the former made by the deltoid. Mr. Keate immediately placed his thumb on the main artery: several others bled profusely, so that three or four ligatures were applied previously to that which secured the axillary: the latter artery was divided obliquely from above downwards. This being tied, eight or ten ligatures were required on smaller vessels before the hæmorrhage was arrested. All the ligatures were cut close to the parts on which they were applied, about ten ounces of blood being lost throughout the operation. An examination was now made with the finger to ascertain the extent to which the bone was diseased, in doing which an abscess of considerable size was opened, situated between the neck of the scapula and ribs, from which pus escaped. The neck of the scapula, spine, and coracoid process, were found to be carious. From loss of blood, the extreme irritability of the patient, and extent of disease, it was deemed advisable not to proceed further with the operation, but to dress the surface of the wound with lint, which was accordingly done, the flaps being brought in apposition by strips of adhesive plaister. Some simple dressing, compresses, and bandages, secured the whole, and the patient was sent to bed.

So great was the resistance offered by the patient, that on one or two occasions it was impossible to keep up the pressure on the subclavian artery, and Mr. Keate held the divided vessel for some time between his finger and thumb. The parts were every where infiltrated with lymph and serum, so that the tenacula, when applied, frequently lost their hold.

A section of the head and shaft of the bone was afterwards made in a longitudinal direction. The head and upper part of the shaft was of its natural size, but the middle and lower part of the latter, towards the elbow, was much diminished. Here the outer shell was thin, and the cancelli

bloody and easily turned out from their situation. The upper portion of the shaft of the bone, together with the epiphysis or head, was filled throughout with the yellow deposit commonly seen in scrofulous bones; the line of demarcation between this and the bloody cancelli below being very distinct. The cartilage of the head of the bone was completely destroyed; the carious surface of the bone being exposed. A soft pulpy substance, of a purplish red colour, two or three lines in breadth and an inch in depth, proceeded from the surface of the head into the cancelli beneath. The muscles of the limb were wasted, and of a pale colour.

Mr. Brodie's remarks on the case were nearly as follows:—

You will have the opportunity of seeing the appearances presented by the section of the diseased bone, as it will be handed round to you for that purpose. The bone is soft, with a yellow deposit in the cancelli, and the disease is of that kind which I have described under the name of scrofulous. The disease has not been confined to the head and shaft of the humerus: the scapula partakes of it; a portion of that bone being dead, and the cartilage of the glenoid cavity being completely destroyed by ulceration.

The patient has laboured under the disease between two and three years. He came to London, and was under the care of a gentleman who is now present (Mr. Guthrie). Under Mr. Guthrie's treatment, every thing seemed to be going on favourably towards a cure. All the symptoms subsided, and he left London with the shoulder-joint beginning to be anchylosed. You well know that anchylosis is the best thing that can happen where the cartilages of a joint are destroyed by ulceration, and that no dependence can be placed on the cure unless anchylosis has taken place. After his return to the country, the patient, in an evil hour, placed himself under the care of a person whom he describes as a bone-setter; who, finding the joint anchylosed, undertook to restore its mobility. For this purpose, he moved the arm with such force as to destroy the adhesions which had taken place. The consequence was a fresh attack of inflammation, and the formation of extensive abscesses.

When the man had been for some time in the hospital, and it was evident that the disease could not be relieved by common methods, it became a question whether an operation might not be resorted to with advantage. A year or two ago, in a case resembling this, I attempted to remove the diseased joint by excision, but the result has been far from satisfactory. The patient, to this day, lingers about the hospital with abscesses still open, exfoliations of the scapula occasionally taking place, the limb useless, and the general health in a bad state. Mr. Babington also, about the same time, performed the same operation on a patient with disease in the shoulder-joint; but, although here the disease was of much smaller extent, and the circumstances altogether more favourable, the patient (if I am rightly informed) still suffers from open sinuses and occasional small exfoliations. The experience which we have had in this hospital, as to the excision of the shoulder-joint, did not, therefore, offer me much inducement to repeat the operation in this man's case. My colleagues were of the same opinion as myself, and we agreed that it would be much better to proceed at once to the removal of the whole limb by amputation at the shoulder. Some years ago I had performed this last operation, under somewhat similar circumstances, with success. A young gentleman suffered from caries of the shoulder-joint. Some large abscesses formed, and burst externally. The case, for some time, did not appear to be hopeless, but at last some large arteries became ulcerated; the patient was exhausted by repeated hæmorrhages, and I was driven to the amputation of the limb as the means of saving the patient's life. After the limb was removed, I found the glenoid cavity of the scapula ulcerated and deprived of its cartilage. The bone was soft, and I cut off the diseased portion of it with a common scalpel. The patient recovered without a single bad symptom. This was seven years ago, and he has continued well up to the present hour.

The operation of amputation at the shoulder is, under ordinary circumstances, one of the simplest and most expeditious in surgery. But in this instance it was rendered very difficult, and I may say hazardous, in consequence of the patient

having no sort of control over himself, and struggling in such a manner that he could scarcely be held by those who assisted me. We must not attribute this altogether to want of nerve and resolution, for you will observe that the parts which the knife divided had been all for a long time in a state of inflammation. The pain of dividing soft parts, which are in a healthy state, is sufficiently severe, but where they are in a state of inflammation it is aggravated three-fold, or more than this. You know well how much the patients suffer during that operation, which you so frequently witness in this hospital, of cutting down on the tibia, and trepanning it, for necrosis; and the state of the soft parts in this case, was nearly similar to what you find in these cases of necrosis.

Our original plan was, that the limb should be amputated first, and that I should afterwards saw off the diseased portion of the scapula. But, partly from loss of blood and partly from the violent struggles which he had made, the man not to proceed to the second part of the operation. A considerable portion of the scapula adjoining to the shoulder-joint is actually dead. I have dressed the surface of the wound, down to the dead bone, with lint; and I trust that it will ultimately exfoliate, and that thus a cure may be obtained. It would, undoubtedly, have been more satisfactory if I could have done the whole of what I originally intended, but the thing was impossible; or, at all events, it could not (under the peculiar circumstances which you have witnessed) have been accomplished without considerable risk to the patient's life.

Nov. 29th.—The patient has done extremely well, and there is every appearance of his recovery. Should any thing occur to change the prospect, we shall record it.

NEW SPECULUM.

To the Editor of the Medical Gazette.

Sir,

If you will take the trouble to refer to my letter containing the sketch of a speculum, which I sent for publication last week, I think you will find that my name is Patrick Mollison, and not J. Thos. Elliot, as the printer has so ingeniously made it out; and yet I do not altogether blame him, as, on considering my usual style of signature, I find that, improbable as it may appear, there really is a certain resemblance between the names, which is more than sufficient to satisfy the judgment of the nimble-witted unhesitating compositor. As this has caused some confusion to Mr. Thompson, the surgical instrument-maker who manufactures the instrument, and also to myself, I shall feel obliged if you will give this a place in your next number.

I am, sir,

Your very obedient servant,

Patrick Mollison.

THE PRINTER OF THE GAZETTE *versus* DR. ELLIOTSON.

To the Editor of the Medical Gazette.

Sir,

The Lancet of last week having repeated the statement attributed to me by Dr. Elliotson, in his address to his class regarding his discussion with the Medical Gazette, I shall feel obliged by your allowing me to record my positive and unqualified contradiction of it, whether proceeding from him or Mr. Wakley. The passage I allude to, is that in which Dr. E. mentions, as one reason why you should not have controverted any thing he said, that the "publication of his lectures, *as the printer of the Gazette informed him*, had 'doubled the sale.'"

The only circumstance of which I have any knowledge, as the possible source of this erroneous assertion, is, that some time ago I happened to mention that the Gazette was rapidly increasing in circulation, and that there had lately been an increase of nearly a thousand in the number printed. That this is what I really did say, Dr. Elliotson admitted, indeed, on a subsequent occasion: I refer to a conversation in the course of which he voluntarily paid a very high compliment to the correctness of the reporter of his lectures: he observed, that the "*medical booksellers*" had told him that the sale of the Gazette had increased lately nearly a thousand; and added, "*I believe you also told me so yourself.*"

I shall content myself with simply declaring that I said not one word that could lead Dr. E. to suppose that I attributed this increase in any particular manner to his lectures, although, as you are well aware, I might assign good reasons why I *could not* have said so. The inference, therefore, which assumes the rise in the circulation of this journal to be attributable to them

alone, is wholly and exclusively Dr. Elliotson's.—I am, sir,

Your obedient servant,

E. C. WILSON.

57, Skinner-Street, Nov. 27.

P.S.—I think it right to observe that I am far from supposing that Dr. Elliotson attributed to me the above statement with the knowledge that it was incorrect. I conceive the impression on his mind to have been, that, previously to the time from which I dated the rise in the circulation of the Gazette, it did not exceed a thousand, and that therefore he considered he had come to a right conclusion when he stated that it had "doubled." It may be as well, however, that he should be informed, that to have doubled the sale would have required a much larger number than the increase he is pleased to suppose was produced by his lectures.

MEDICAL & PHYSICAL JOURNAL.

THE Editors of the Medical and *Physical* Journal present their compliments to the Editor of the Medical Gazette, and will feel obliged to him if he will do them the justice to state that the "encomium" published in the last No. of the Gazette, and headed "Medical Journal," was not published by them. The Editors would be quite distressed to deprive the Editor of the Medical and *Surgical* Journal of the *merit* of the article referred to, and they are equally anxious to protect themselves against the imputation of thus indulging in personalities, from which they at all times studiously abstain.

Nov. 28, 1832.

[We regret that we should not have designated the periodical with sufficient precision. We cannot, however, for a moment admit that any one would suppose *such* an extract could have been taken from the pages of our esteemed contemporary—the Medical and *Physical* Journal. —ED. GAZ.]

LONDON UNIVERSITY MEDICAL SOCIETY.

IT appears that there is an association of pupils so called, and that they take in certain periodicals for their edification. Now Dr. Elliotson having declared war against the Gazette, it was very naturally thought by some of his pupils that it would be highly gratifying to their Professor if they were to discontinue it, and accordingly a motion to that effect was unexpectedly proposed about a fortnight ago, and carried, notwithstanding the opposition of a considerable number of the members. Before their next meeting, our answer to Dr. Elliotson had appeared, *when the former decision was reversed.* But we understand that the question is to be brought forward at the next general meeting. We take leave to recommend, that on this occasion all those young *gentlemen* who are moved with virtuous indignation against the personalities and scurrility of the Gazette, and who approve of the freedom from those vices displayed by the Lancet, should as a point of conscience vote in all things in favour of the latter, and against the former—they will thus be called fine independent fellows by Wakley; and if they follow in his steps with diligence, and adopt his principles with zeal, it is just possible that in time they may come to be as respectable, and as much respected, as that worthy himself.

CUTANEOUS DISEASES.

PUSTULÆ.

VACCINIA - COW-POCK.

Identity of Cow and Small-pox.—The next disease, gentlemen, of which I shall speak, is one which is put, by Drs. Willan and Bateman, in the order vesiculæ—viz. the cow-pock; but although there are only vesicles at first, the contents become so turbid that at last there is genuine pus; and I think it is much more consistent altogether to put it in the same order with small-pox. Indeed the cow-pock is believed by many to be nothing more than a modification of small-pox—to be merely the small-pox, modified by passing through the cow. There can be no doubt that small-pox is an affection which cows, and perhaps other brutes, may have. You most probably have seen the accounts lately published in different journals, of some experiments that have been made with a view of ascertaining this point. Clothes have been taken from patients labouring under small-pox and laid on cows, and they have had the disease called *cow-pock*. If the disease be really small-pox, modified, we then see no wonder in the circumstance of it generally affording immunity from that disease to those who have it. The disease, however, of cow-pock is far milder than small-pox, and it is strictly a contagious disease; it cannot be communicated by infection, as small-pox may; it is only communicated by palpable matter.

Symptoms.—The disease, given artificially, begins a few days after the poisonous matter has been inserted into the body. By a slight scratch, or by a wound of any description, a small transparent pearl-coloured vesicle is formed, with a circular or somewhat oval base; the upper surface being more elevated at the margin than at the centre till the end of the eighth day, the margin itself being red, turgid, shining, and roundish, so that it often extends a little over the line of the base. The vesicle contains clear lymph in little cells that communicate with each other. About the eighth or ninth day it is surrounded by an areola, varying in diameter in different cases, from a quarter of an inch to two inches, and is usually attended with a considerable tumor and hardness of the adjoining cellular membrane. The areola declines from the twelfth day. The surface of the vesicle then becomes brown in the centre, and the fluid concretes into a hard round scab. The colour afterwards becomes black, and so it may remain for two or three weeks. There is also left a permanent cicatrix about four or five lines in diameter (this it is important to remember), the surface being marked by pits denoting the number of cells of which the vesicle has been composed.

The vesicle, you will remember, is formed about the sixth day after the insertion of the virus; about the seventh or eighth day there is an inflamed areola—a swelling and hardness; and it is on the eleventh day that all the symptoms decline. The vesicle then becomes muddy, and darker. If there be any pyrexia of the system, it occurs about the eighth or ninth day. Now and then (and I have seen such a case myself) the disease has nor appeared for two or three weeks after vaccination; and then suddenly the disease has begun, inflammation has taken

place, and the affection has gone through its regular process.

Necessity of the Disease going through its regular Course.—Now if there be a violent degree of inflammation, or if the disease vanishes too rapidly, or if there be any variation from its proper course, you must not imagine that any security is given from the small-pox. If, on the one hand, there be too little inflammation, so that the affection soon subsides, and no genuine vesicle is formed; or if, on the other hand, there is too violent an inflammation; then, in either case, you may doubt whether the disease will be of any use. Nay more, if the cicatrix, after the disease has appeared to go through its stages properly, is not of the description which I have now mentioned—if there be not a permanent cicatrix about five lines in diameter, a little depression with very minute indentations—you may then suspect that the disease has not been perfect. You may recollect my having mentioned, that, in the case of all contagious diseases, you may have a disease of the greatest mildness or the greatest severity. A contagious disease will not only vary as to the time at which it appears after the virus has been applied, but it will vary as to the time in which it goes through its course, and it will vary as to its degree; so that I am satisfied that the plague will sometimes occur with only a slight indisposition: and we continually see gonorrhœa so mild as to last only twenty-four hours; whereas, in other cases it will be so severe as to last some weeks. Now this general fact is strikingly shewn in cow-pock: you continually have it die away from the disease not being fully formed, and, on the other hand, you sometimes have it so very violent that the whole course of the affection is disturbed. Nothing should occur for twenty-four or perhaps forty-eight hours; and then there should be a little irritation: a vesicle ought to be gradually formed; on the seventh or eighth day there should be an areola, and all the symptoms should decline on the eleventh day. When it is all over, you ought to see a dark and hard scab for two or perhaps three weeks, and then a permanent cicatrix should be left, with little indentations arising from the cells of which the pustule has been composed.

Immunity afforded against the Small-pox.—This disease, in the greater number of cases, gives immunity from the small-pox; and where it fails, which it frequently does, the small-pox is, in the greater number of instances, milder than it otherwise would have been. In general, when that disease occurs after cow-pock it suddenly stops; it is ushered in by great pyrexia, and then, about the sixth day, it suddenly declines.

I believe I mentioned that the effect of inoculation for small-pox was not of this description; that it caused the disease to be produced with a smaller number of pustules, whereas vaccination did not lessen the number of pustules, but shortened the course of the disease, so that about the sixth day all the violence generally ceases. This, however, is not a universal occurrence, because some patients die of the small-pox after they have had the cow-pock. At first it was imagined that cow-pock was a certain preventive of the small-pox; however that was a hasty conclusion: because it prevented the disease for a certain time, and in the majority of cases, that afforded no solid basis from which to infer that it would prevent it in all cases, and for the rest of life; further experience was necessary before such a conclusion could with propriety be drawn. But we may now safely assert that a great number of persons who are vaccinated escape the small-pox; and where persons do not escape, the greater number of them have the disease very mildly. I believe the whole of the matter comes nearly to that.

Produces only a single Vesicle.—This disease produces only a single vesicle or pustule; it does not produce a number all over the body as small-pox, and other pustular diseases, do.

Mode of Vaccinating.—As it is very desirable that the disease should be fully formed, and the constitution thoroughly affected by it, it is the practice to make several insertions of the matter, perhaps two in each arm. The arm is as convenient a place as can be chosen, and it is usual to make two wounds in it. The lancet should be held so that the matter may gravitate into the wound.

Treatment.—There is no treatment required in this affection, unless you choose to give the child a mild aperient.

History of Cow-pock.—As to the origin of our knowledge of the effect of this disease in preventing the common form of small-pox, I may mention, in a few words, that we are indebted for the publication of the fact to Dr. Jenner. In 1768, when he was apprentice, he learned by report that the cow-pock on the hand of milkers prevented them from having the small-pox; and he very frequently, at his master's, had to dress the hands of such persons. From his inquiries he satisfied himself that the ulcers he dressed were derived from the teats of cows. He learned too, that it was very well known in that part of the country, among the peasants, that persons who had these sores upon their

hands could never be made to take small-pox by inoculation.

In the further prosecution of his studies he came up to London; and having returned to the country and settled there as a surgeon, he commenced a series of inquiries into this matter. He found a very considerable number of persons insuseeptible of the small-pox; and in all these cases he was assured that the persons had had the cow-pock. The oldest farmers, however, said that the idea was not known in their younger days. Notwithstanding this insusceptibility which he found among so many persons, he met with exceptions; and he found some who had had those sores, and yet afterwards had the small-pox. Some medical men of whom he made inquiries believed the fact, and others disbelieved it. He found the difficulty cleared up in a great measure, by ascertaining that there were several sorts of sores arising from cows' teats, which were communicated to those who milked them, but that there was only one which was the genuine cow-pock. He likewise had to encounter another obstacle: from the influence of external circumstances the cow-pock among the cows ceased, and he was unable to make any experiments on the subject. I mentioned, when speaking of contagious diseases in general, that affections, respecting the contagion of which there can be no doubt, will sometimes cease, and sometimes cannot be made to spread, merely as it would appear from certain external circumstances. Now cow-pock, which is only contagious, not infectious, is said to have so ceased, that it was impossible for Dr. Jenner to get matter to make experiments. However, in 1796, the cow-pock broke out in a dairy-maid, whose finger had been scratched. From this finger he vaccinated a boy, and regular cow-pock was produced. He repeated the experiment on another, taking the virus from the human subject, and he then likewise produced the disease. He mentioned the facts to several of his medical friends, and prepared a document to lay before the Royal Society; but he was advised in kindness and true friendship not to expose himself by communicating any such nonsense, merely because it was new. However, he persevered; he did communicate his knowledge to others; and just the same fury was excited among medical men that had been excited formerly, when inoculation was first made known to them. It was said that it was taking the power out of God's hand—that God gave us the small-pox—and that it was impious to interrupt it by the cow-pock. When I was a boy I heard people say that it was an irreligious practice; that it was taking the power out of God's hand, forgetting that it was merely using that power which God has given to us. Sermons were preached for it and against it, and hand-bills were stuck about the streets. I recollect seeing it stated in a hand-bill, that a person who was inoculated for the cow-pock had horns growing in consequence of it. Many were said to have died from mortification produced by this practice. One of the surgeons at St. Bartholomew's Hospital—there being no clinical lectures then—used to give gratuitous lectures against the cow-pock, in which he advised all the students not to resort to such a practice. He was interred in this city, and by his direction a tablet was erected to his memory, on which was inscribed, that he was all his life strongly opposed to *cow-pocking*. His rancour did not cease even with his death. It appears that a great want of principle was manifested; that an account was forged setting forth a number of deaths as having arisen from the disease, and the greatest lack of candour was displayed. After a time, however, all this ceased; and now I need not say that it is a regularly established practice, although it certainly does not deserve such encomiums as Dr. Jenner supposed it did. It is not an absolute preventive of the disease, but it does prevent it in a large number of cases; and where it does not, it generally makes it much milder.

I have already stated that, with regard to treatment, none at all is necessary; and I will not take up more of your time respecting its details, because if you consult Mr. Moore's History of Vaccination, which is almost as amusing as a novel, you will there find every thing that I can tell you respecting it.

Varicella.

There is another disease very much allied to all these, and which is called the *little small-pox*, varicella, or, in common language, the chicken-pock, or swine-pock; but which requires no treatment in general, any more than cow-pock.

Symptoms.—The chicken-pock is chiefly important as being liable to be mistaken for small-pox; but in itself it is totally unimportant. The affection begins as a vesicular disease, but there are continually some pustules. There are, however, fewer pustules than in small-pox, and for the most part they do not amount to more than 200. They go through their course too with far greater rapidity than small pox, and there is very little irritation of the system—frequently none at all. It is sometimes a difficult matter to distinguish between it and small-pox; but when you consider that the disease has far fewer pustules, that it generally runs through

its course with great rapidity, and with scarcely any disturbance of the system, there is no great difficulty in making the diagnosis, more especially if you know that the child has had the small-pox before.

It is said that in chicken-pock there is always cough; that there never was a case occurred without being attended by some degree of cough. It is a contagious affection, and there is a little feverishness before the disease takes place; but in about six days the whole is over.

Identity with Small-pox.—Some have imagined that this disease is only a modification of small-pox; that it is only a milder form of the disease, called modified small-pox; but I will not give any opinion on the subject, because I do not think that we have sufficient observations on these various diseases to enable us to speak with any degree of certainty. After this disease I have frequently seen ecthyma and rupia take place, just as after small-pox; and sometimes there have been scars, just as in small-pox. I had the small-pox myself, and was not pitted at all, but the chicken-pock came afterwards, and left several pits; so that the disease occasionally produces pitting here and there the same as small-pox.

Dr. Willan has given some representations of the disease, in his plates. It occurs in two or three forms; you see very small pustules; it is easily distinguished from small-pox by the disease being in its genuine character vesicular. Now and then, however, there are pustules, and now and then there is pretty smart feverishness. The best description of this disease is contained in Dr. Heberden's Commentaries, and the account is very well worth reading. It is only important to know that there is this disease, because people frequently think that their children are going to have the small-pox when they are not. If the patient be scarcely ill at all, and has a crop of pustules of this description, you may be almost sure that it is the chicken-pock which is about to occur. There never is, I believe, any internal affection of any consequence when this disease exists. In very rare cases there is violent pyrexia, headache, delirium, and even convulsions; but they are all transient. There is no severe affection of the larynx, of the bronchiæ, or of the intestines, as in many other cutaneous diseases.

Acne.

Those eruptions of which I next proceed to speak are not placed by Bateman with pustular, but tubercular affections, because there is a considerable hardness of the skin. The fact is, however, that suppuration takes place for the most part in these affections, if they last long, and I therefore prefer arranging them with Rayer as pustular diseases. There is only this difference in them, that there is what may be called slow chronic pustules instead of acute ones—they are *blind*, as people commonly say.

The first of these to which I will allude is called by Bateman and Willan *acne*, and by Rayer *couperose*. It is a disease exceedingly common, and not at all contagious, nor is there the least harm in it. It occurs particularly in young men and women, especially the former, and prevents them from being very handsome about the period when they wish to look the best. Sometimes the face will be affected with this disease for four or five years.

Varieties.—It now and then appears with little black specks in the midst of rather hard elevations, and then it is called *A. punctata*. Sometimes there is very great hardness, and it is thence called *A. indurata*. In the ordinary form it is called *A. simplex*, and is described by Bateman to be an eruption of small pimples, not very numerous, without much inflammation, the surface between the pimples being perfectly healthy; only that there is a little roughness of the face. It now and then occurs, causing the sebaceous follices to be large and distinct, and marked with a black speck on the top, and then it is called, as I have just said, A. punctata. By squeezing them, you force out what is called a *maggot*, but it is only the contents of the sebaceous follicles; and by continued squeezing, you may force out stuff as long as the follicles will supply it. It occurs almost solely in the face: it will take place in the neck, but the face is its usual seat. Many people have a little of this affection, but some have it very severely. There is no occasion to remember the particular names; sometimes there are black specks, and sometimes there is a good deal of redness around them. Now and then it occurs with considerable redness and prominence of the skin around, so that you may discover each particular vessel, and from its redness it is called *A. rosacea*. You will see this in middle-aged and elderly persons; and in this form the maggots lie in a bed of roses. This is a very permanent complaint: I do not know that it is often got rid of; but, luckily, it does not occur till late in life; and it is taken for granted to be an outward and visible sign, not of *spiritual*, but of *spirituous* graces. Every person is set down for a tippler who has such a nose as is represented in this plate, (pl. lxiv. of Willan.)

Each of these hard inflamed pimples of

the skin may suppurate. Some will subside after a time, but a great many suppurate, and if they do not, it is an instance of termination by resolution, and we ought not the less to call it a pustular disease; because, if it pursue its course—if it be not arrested by something or other, it goes on to that end;—if it is not resolved, suppuration is the termination of it.

Treatment.—There can be no doubt that when these pimples are small, it is much the best practice to squeeze them, and empty the contents. If this be done, the tubercle will for the most part subside; and of course, if they suppurate, the sooner the matter is let out the better. I am not aware that internal medicine has any effect on the disease; but I have seen great benefit arise from the application of stimulants, and one of the best is the ointment of the nitrate of quicksilver rubbed well upon the part—yellow citrin ointment, as it used to be called. This stimulates the disease, which seems to be one of inaction. Of course, if it stimulate too much, cold applications should be applied, and the irritation diminished. You sometimes find this ointment too strong, and then it is necessary to dilute it with another—with simple spermaceti if you please, or zinc ointment. Some people give sarsaparilla and nitric acid in these complaints, but I do not know that they do any good, nor do I know that Plummer's pill is serviceable, but I think I have seen benefit from tar water. The best local applications are the stimulating substances that I have now mentioned. I have seen the face swollen all over when they have been employed, and of course, if any very great inflammation come on, that must be treated in the ordinary way.

Sycosis.

Then there is another disease which occurs in the face, but not so much about the nose and the parts of the face destitute of hair, as upon those parts which are covered with hair. It takes place particularly in the beard of men about the chin, and from its situation it happens to be called *sycosis.*

Varieties.—When it occurs on the chin it is called *S menti.* If it occur about the margin of the hairy scalp, it is called *S. capillitii.* There is, however, no occasion to make a variety because it occurs in these different situations; you might as well make varieties of rheumatism accordingly as it attacks the shoulders or the knees.

The tubercles in this disease are not as hard as in acne: they continue for a length of time, and they are more inclined to suppurate. It makes shaving an unpleasant operation, notwithstanding you have a good razor, a good strop, good soap, and warm water. These affections are merely slow chronic pustules, and the complaint is exceedingly obstinate.

Treatment.—I have not seen the disease much relieved by bleeding, either general or local, or by the exhibition of mercury; but, of course, there are cases where antiphlogistic measures are proper. I have seen it subside from the administration of iron; but, for the most part, all sorts of applications fail. You may apply stimulants, and after a time they do no good; or you may apply cold soothing applications, and after a time they lose their effect.

It is absurd to call these tubercles, for there is simply inflammation; there is no tubercle—no organic change in the skin. The gentleman represented in pl. lxv. of Willan must have regretted having a beard. Acne is disease of the follicles, and it is frequently attended by extreme hardness, whereas sycosis is not so hard. I really do not know what to recommend in the disease; every one must be left to his own judgment. I have been tired out and out by the treatment. Rayer gives a drawing of both these affections.

Of course, as this is a disease which principally occurs in the beard, women are exempt from it, unless their ovaries begin to dry up, and they acquire the character of men; but it does not occur where there is no hair. Both these diseases are confined to the head; acne to the face at large, and sycosis only where there is hair.

DISEASES CHARACTERIZED BY BOILS.

The other pustular diseases of which I will speak, are not treated of by Willan and Bateman, but they are all, or nearly all, spoken of by Rayer; one, however, to which I will draw your attention, is not spoken of by him. Rayer makes a distinct class of those diseases which are disposed to gangrene. Now and then plague is attended by pustules on the skin; large ones, indeed, such as are commonly called boils, and there is a great tendency to gangrene. The same occurrence takes place in the disease called *pustule maligne*—malignant pustles, which are generally communicated from brutes. He makes a separate class of these, but they are merely suppurations, and I therefore think that they ought to be classed with the pustular diseases. However, if the suppuration be very considerable, not merely pustules, but a very large suppuration, it may only lead to confusion to speak of them in that way; and it is to be remembered that they are not mere pustules, but that the cellular membrane is chiefly implicated, and the skin only secondarily. Still, however, as the disease occurs on the surface of the

body, it is well to consider it as an affection of the skin.

Now the most simple affection of this description is a sty of the eye; then a more severe one is boil, in which there is a disposition to gangrene; and then another is carbuncle—common carbuncle, in which, however, there is a strong disposition to gangrene. These three diseases, not one of which is mentioned by Willan and Bateman, Rayer puts together, and calls them boily diseases—diseases characterized by boils. A carbuncle is only a large boil, but it is of such an extent that surgical aid is necessary to let the matter out.

Then he makes another sort, which differ only in their tendency to gangrene, and these are maliguant pustules, which he includes among the *inflammations gangreneuses*;—and the plague itself. To these may be added another, namely, the glanders of horses, which may be communicated to the human subject.

With respect to sty, boils, and carbuncles, I shall say nothing, because they are spoken of in the lectures on surgery. Those of which I shall speak are malignant pustules, the plague, and glanders. As to the plague, it is a disease not confined to the surface; but, then, many affections called skin diseases, are not confined to the surface. Such is the case with small-pox: it is a general affection of the system, and involves the skin among other parts. Now the characteristic of these suppurations is a disposition to gangrene. In respect to all these diseases, whether small ones, such as sty and boil, or great ones, such as malignant pustules and plague, they bear the same relation to porrigo and bullæ, that those do to the small vesicles of herpes. I said that I thought it wrong to separate them; and so with respect to these, I think it a pity to make different classes merely on account of their size. Because small-pox and porrigo have small suppurations, and plague or carbuncle is characterized by a suppuration of large extent—more magnified, it is no ground for constituting a different class of diseases. You will recollect that they are merely pustular diseases, with suppurations on a large scale.

PLAGUE.

The first of these diseases of which I will speak is the plague.

Symptoms.—Now the plague is very similar to typhus and continued fever; but it so affects the surface of the body that I have thought it well to speak of it among diseases of the skin, as Rayer has done. It is, like many other diseases of the skin, an acute fever—as in the case of small-pox, for example. It is an acute fever, attended by headache, delirium, and a burning sensation at the epigastrium. Perhaps there may be great strength of body at first—the person may be of a full phlogistic diathesis—but great debility soon comes on, and very often there is debility from the first. Glandular swellings speedily appear in the arm-pits and groins, so that the disease is characterized by buboes; but the glands of the groins are more frequently affected than those of the arm-pits. Sometimes these glandular swellings or buboes come on at the first, and sometimes not till towards the end of the complaint. Besides them, however, there are upon the surface vesicles of all sizes, the contents of which are frequently dark. There are upon the surface, boils, carbuncles, and vesicles; and between them, and even where they do not exist, there are often vibices, petechiæ, and ecchymoses. These petechiæ, it is said, will sometimes rise into carbuncles; where at first there was merely a little effusion or congestion of blood, there will at last sometimes be carbuncles: occasionally there is not sufficient power of the constitution—not sufficient strength of inflammation for carbuncles and buboes to arise. Just as in the case of the violent application of malaria, or the violent application of the poison of typhus fever, and also as in cholera, persons will sometimes die immediately, without any reaction taking place.

Fatal tendency.—The plague usually destroys life in from two to five days; but if a person survive the fifth day, recovery is generally expected. Most people die who are seized with this disease, even though they enjoy every advantage of treatment and comfort. It is said that the disease may be had more than once.

Antiquity of the Disease.—Some consider it a very ancient disease: the symptoms are mentioned by Hippocrates, and Dr. Bancroft contends that the disease is mentioned in the Bible; that this was the affection under which the Philistines laboured when they are said to have been smitten in the private parts, after taking away the ark. He says that the disease spread as they carried about the ark—that it was a contagious disease, and the more they carried about the ark the more the disease was communicated, till at last it spread from Ashdod to Ekron. He considers that the Philistines probably received the disease from Egypt. Some consider, that, as the Philistines were smitten in the hinder parts, they were afflicted with piles; but Dr. Bancroft contends that piles would not have killed them in the way in which they perished. However, I think there is this objection to Dr. Ban-

croft's argument that it was the plague—if you read the book of Psalms (as people ought to do, and all other parts of the Bible), you will there find it said, that they were not only smitten in the hinder parts, but put to a *perpetual* shame: and therefore a chronic disease was left; but the plague would not leave a chronic disease of that description. It is stated, that from 50 to 70,000 persons were smitten by the disease. But whether Dr. Bancroft be right or wrong, the symptoms were distinctly mentioned by Hippocrates. It is a disease that is almost always prevailing in the Mediterranean, at Constantinople, Venice, and all the various parts of that sea. It has likewise prevailed at Marseilles, Moscow, and London.

Proofs of its Contagiousness.—There can be no doubt whatever of its being a contagious disease, but it is rarely communicated without contact. It is for the most part believed to be a contagious disease in the strict sense of the word; not infectious. One of the latest writers upon it (Mr. Madden, a surgeon) says, that if the air be close—if there be no ventilation, no cleanliness, and the emanations from the patient are very much concentrated—it may be communicated by infection; but if there be any ventilation at all, then it can only be communicated by contact—contact with the individual or something that he has touched. Some have denied, of course, that this disease is contagious; but there are proofs without end that it is. When the French army were in Egypt, about eighty medical officers died of it in one year. The next year they employed Turkish barbers to dress the patients and bleed them, and then only twelve medical officers died; but one-half the barbers died: however, it was a very good change. It is said, that at Moscow, in 1771, all the assistant-surgeons were seized with it, amounting to fifteen, of whom three died; but the physicians, who did nothing but walk through the wards with a pen in their hands, generally escaped: the assistant-surgeons, however, were reduced to the same state as the barbers. At Marseilles there had been no plague for fifty years, till 1720, when an infected vessel arrived. The disease at that time was distinctly traced to the arrival of an individual from an infected spot; and half the inhabitants died in a short period after the arrival of the infected vessel. At Moscow, it is said that the plague had not been known for 150 years, till they had war with the Turks, and two soldiers from an infected place arrived and died; after which, 80,000 perished from the disease in the city, and 20,000 in the neighbouring villages. In 1813, it is said that the plague had not been known in Malta for 137 years previously, and then the disease was brought from Alexandria. Howard says that the plague of London, which occurred in 1665, was conveyed to a village in the Peak of Derbyshire by means of some old clothes. He was so astonished at the absurdity of many medical men denying that it was contagious, that he writes as follows:—"Have not some of our professors sullied their names with the dangerous doctrine of the non-contagion of the plague? From no other cause than the error of the physicians, who constantly maintained that the disease then epidemic was not contagious, happened that terrible visitation which, in 1743, ravaged the city of Massina and its vicinity, with the loss of above 43,000 individuals in the short space of only three months." If you look into most writers you will find that persons who attended others labouring under the disease suffered, while those who ran away escaped it. The Turks are so satisfied of its being contagious, that when the disease prevails they shut themselves up, and the Pacha holds communication with no person whatever. I think there can be no doubt of the plague being contagious, in the strict sense of that word.

Atmospherical Influence.—However, it is remarkable that great heat and great cold will stop it. It is a disease that will not bear great heat, so that it has never been known to occur in tropical climates; so that when the heat has arisen to a certain point, it stops. This takes place in Egypt about the 24th of June; and as that is the nativity of John the Baptist, he has the credit of putting a stop to the plague; the Catholics ascribe it all to him. From the intense heats it is said never to appear in Upper Egypt; and it ceases altogether as the hot weather comes in. The winter also causes almost a complete cessation of it, and frequently renders exposure to a person labouring under it perfectly harmless. From its being so contagious a disease, Dr. Wells considered that it was owing to quarantine laws that we are not now troubled with this pestilence. He says that many persons ascribe our exemption from the disease to the fire of London; but he contends that the plague has not been known in London since 1665, whereas the fire did not take place till 1666. He says that the fire of London consumed only one-fifth of the town, leaving the Borough, Wapping, Whitechapel, Clerkenwell, St. Giles's, and the purlieus of Smithfield, untouched, which were among the dirtiest places. He says, secondly, that Bristol has escaped for the same length of time as London, and yet there has been no fire in that city, and the improvements there began much later than in London. He then says, the

Dutch are as cleanly as we are, and yet the plague continued there forty years longer than in England. Next he instances the town of Craeow as a beastly place, and yet there has been no plague there for a century. Fourthly, he says that ague alarmingly increased, and returned eleven years after the fire, and that dysentery continued till the end of the century, notwithstanding the improvements; and therefore he argues *à fortiori*, that as they could not prevent dysentery, they could not prevent the plague. Fifthly, he says that the plague is not known in India, China, and North America, where in many places they are filthy in the extreme. Sixthly, he says the plague began first among the poor, who associated with the sailors of infected vessels. But he contends, that from the time the quarantine laws were established, the plague has been unknown in England; and from the considerations I have now stated, the circumstance could not arise from the increased cleanliness and general improvement of London, but from the strict adherence to quarantine laws.

I need not repeat to you some facts which I mentioned when speaking of contagion, to shew that this disease was contagious. Dr. White, I told you, inoculated himself and died. You will find instances of this given in Dr. Heberden's Medical Commentaries.

Period of Incubation.—When the poison has been applied, the disease generally appears in from three to five days.

Not Communicable by Dead Bodies.—It is said that the disease is rarely caught from a dead body. I mentioned, when speaking of the innocuous agency of putrified animal matter, that Howard stated that persons did not suffer from the stench of putrifying dead bodies of persons who had perished of the plague. I believe persons may touch the dead bodies without fear of catching the disease, but touching their clothes is another thing. It is said by Dr. Bancroft, that the Turks employed by the French to bury the dead all escaped, with the exception of one individual. Howard says, that in Turkey people are not afraid to handle the dead bodies.

Treatment.—As to the treatment of the disease, I believe that one-half of those who have it perish, and therefore you may suppose that the treatment is not very successful. But we are told that the treatment must be conducted on the same principles as in common fever. If there be a phlogistic diathesis, active bleeding, cold affusion, and calomel, are recommended; but, on the other hand, when there is debility, we must exhibit wine, quinine, ammonia, and, if Dr. Stevens be correct, the neutral salts in great abundance. Of course those who make one exclusive rule of practice will kill a great many; those who always bleed will destroy a great number, and those who always give brandy will do the same. But Mr. Madden has compared the two modes of treatment. He says, that generally where bleeding has been had recourse to, the mortality has been very great; but where he gave strong brandy and water, and induced a copious perspiration, his success was very great. He also gave enemas of the same ingredients—that is to say, hot brandy and water; he sponged the body with vinegar and water, soaked the head with vinegar, had hot poultices put on the buboes till they gave pain, and cut into the carbuncles to arrest the mortification; and by this local and general treatment he was so far successful, as to save seventy-five patients out of a hundred.

I should suppose that the period for lowering in this disease was very short, and that stimulating treatment was the most superior of the two. The best antiphlogistic treatment would be, not to evacuate blood, but to apply cold water, and purge. I should, from the accounts I have seen, think that active depletion would be very dangerous. The moment softness of the pulse was perceived, I should imagine that the treatment mentioned by Mr. Madden would be very proper.

LECTURES
ON
DISEASES OF THE EYE;

Delivered at the Birmingham Eye Infirmary,

By Richard Middlemore, Esq.

CATARRHAL OPHTHALMIA—CATARRHAL INFLAMMATION OF THE CONJUNCTIVA.

I MENTIONED to you that the mucous membrane of the eye was subject to those affections to which the same description of texture in other situations was liable, and among other affections, to an inflammation producing an increase of its natural secretion, and arising generally from a peculiar condition of the atmosphere. You will often find a disease of this kind very prevalent, and it will be frequently accompanied by other catarrhal symptoms, in which case it is termed an influenza. This state of the mucous membrane of the eye is ascertained to be dependent, in many instances, on a peculiar condition of the atmosphere. It will not be expected that I should on this occasion enter upon

the investigation of that process by means of which the application of cold to the surface, or the occurrence of an altered state of atmosphere, gives rise to the products to which we have just alluded, for it is a subject involved in great obscurity, and would require for its proper elucidation much inquiry and extensive research: we will therefore be content to take the effects as they are presented to our notice, without making any inquiries concerning their cause, or attempting to explain that series and succession of events by which the phenomena designated catarrh are connected, as effects, with those external agents which, we are well aware, give rise to their establishment.

Symptoms.—The earliest symptoms of catarrhal inflammation of the conjunctiva, are, an uneasy sensation of smarting; a slight increase of vascularity, which is least considerable near the cornea; a trivial degree of pain, and augmented lachrymal secretion. The second set of symptoms are—considerable smarting, and a sensation of stiffness on moving the lids; an uniform scarlet tinge of the whole of the sclerotic conjunctiva; greatly increased mucous secretion; and a slight amount of serous effusion beneath the conjunctiva, which is particularly evident immediately around the circumference of the cornea, and also whenever the globe of the eye is moved in the orbit. The third set of symptoms consist of those in which the more important textures of the eye have become affected, either from contiguity or sympathy.

If you see a patient with catarrhal ophthalmia at its commencement, you will observe that the redness is not very considerable; there will be great enlargement of those vessels which are situated at the periphery of the globe; but that part of the conjunctiva near to the cornea will be almost as pale as usual—there will not be that arrangement of pink vessels around the cornea, which is so distinctly witnessed when the iris or ciliary processes are inflamed. The conjunctival vessels at first proceed in fasciculi, by degrees they become much enlarged, others increase in size, they approach nearer to the cornea, until the whole of what is popularly termed the white of the eye, becomes one uniformly scarlet surface. You will remember that the vessels of the conjunctiva are of a scarlet colour, very different from the pink appearance noticed when those of the sclerotica are enlarged; you will also remember that they are loose and may be readily moved about by the finger, or by suddenly altering the position of the conjunctiva, with respect to the sclerotica.

You will not in these cases have much chemosis; there will be a slight degree of serous effusion beneath the conjunctiva, separating it to a certain extent from the sclerotica, and raising it around and above the margin of the cornea, but it will rarely proceed beyond this, certainly not to the extent of producing that condition of chemosis you will notice in purulent and gonorrhœal ophthalmia.

The enlargement of the superficial vessels, by destroying the smoothness of those surfaces which move upon each other, occasions considerable smarting, and gives rise to a sensation such as would be experienced if sand or dust were beneath the lids; but independently of this sensation there will be scarcely any pain—none of that aching and throbbing, or acute and darting pain, which characterize inflammation of the deep-seated parts, unless indeed, the inflammation shall have extended as in what we termed the third set of symptoms; then of course the ordinary symptoms of ophthalmitis will be present, but such a state is not what we are now considering, and is one which will seldom if ever occur, if proper remedies be administered in due time.

Your patient will have at first, increased lachrymal discharge, but by degrees this secretion of tears is diminished, and the mucous secretion becomes gradually increased, so that when the disease is fully developed, the frequent removal of this augmented quantity of mucus is rendered necessary; during sleep it incrusts at the edge of the tarsus, and accumulates in considerable quantity at the inner canthus, so as to prevent the patient from opening the lids when he first awakes, without giving rise to pain, and tearing away some of the ciliæ which are imbedded in the adhesive mucus which collects at the tarsal margins; very frequently strings or patches of this discharge will collect upon the cornea, rendering the patient's vision very defective, and they will often express considerable alarm lest their eye-sight should be lost—you need have no hesitation in allaying their apprehensions, when so excited.

As this mucous discharge decides the catarrhal nature of the disease, and furnishes one of the most striking characteristics by which it is distinguished, it is important that you should be well acquainted with its qualities in the different stages of the inflammation; it will be at first of a thin consistence and of a greyish colour; by degrees it becomes more consistent, and is eventually, thick and glutinous, so as to resemble pus in its external qualities. These are the characters by which it is ultimately distinguished; and you will bear in mind, that its primary qualities, as to colour, consistence, and adhesiveness, will materially assist your judgment when deciding upon the nature of the disease.

You will discover that the palpebral portion of the conjunctiva will, in many instances, have partieipated in the mischief, and that a part of the secretion which incrusts upon the border of the tarsus, and agglutinates the edges of the eye-lids, proceeds from it, and you will also find that the meibomian secretion becomes altered, and that, in short, a slight degree of tinea is present; indeed the palpebral conjunctiva may be primarily affected, and the sclerotic portion of that membrane may or may not be involved; the symptoms will be in many respects the same, except that the vacularity and tumefaction of the lining membrane of the lids will exist, instead of the phenomena we noticed when describing the circumstances which characterized an affection of the sclerotic portion of the conjunctiva; there will also be a greater degree of irritation at the tarsal borders, owing to the inflammation of the meibomian glands, and a consequent change in the qualities of their secretion.

There will generally exist a degree of constitutional disturbance, corresponding to the severity of the inflammation of the eye, and if the mucous membrane of the nose become much and extensively affected, there will be a sensation of weight over the forehead, a certain amount of catarrhal fever attended with occasional rigors, slight cough, increased discharge from the schneiderian membrane, and so on; in short there will exist the symptoms of decided catarrh. Sometimes the uneasiness occasioned by catarrhal ophthalmia is increased during the day, and much relieved during the night, or, if that be not the case, there will be a distinct remission and exacerbation of the symptoms at regular intervals.

Causes.—It has been mentioned, that a peculiar state of the atmosphere is the most frequent cause of the disease under consideration, and that the mucous tunic of the eye is liable to be diseased from many of those agents which exert an injurious influence upon mucous membranes in general; and to this statement it remains to be added, that keen winds, or currents of cold air, applied directly to the surface of the eye, will also produce catarrhal ophthalmia, under circumstances which render it highly improbable that there exists that particular state of atmosphere, which, in the common acceptation of the term, is favourable to the production of influenza, or to catarrhal affections generally; long exposure of the body to cold, without a degree of exercise sufficient to prevent chilliness, or subjecting the surface of the body generally, or of the head or face particularly, to the influence of rain or snow*, or allowing the body to become suddenly chilled by inaction or other causes, after its temperature has been raised by exercise, or increased by sitting in a warm room, or by remaining in a protected situation: sudden and extreme changes in the state of the atmosphere, as to heat or cold, dryness or dampness, are also to be classed among the causes of catarrhal ophthalmia. From this account of the causes of catarrhal ophthalmia, you would naturally expect, that at particular seasons, and in particular districts, it would be exceedingly prevalent, and such is really the case; you will find that at a public Eye Infirmary, for instance, the children of the poor residing in some particular district will be affected in great numbers, and the same occurrence is sometimes noticed in large schools.

Diagnosis.—You would distinguish catarrhal ophthalmia from inflammation of the deep-seated textures, by the absence of acute pain, and much intolerance of light; by the colour, the situation, and the mobility of the blood-vessels; by the state of the pupil, and by the condition of vision: and you would distinguish it from other forms of conjunctival inflammation, by the nature of its exciting cause; by the quality and quantity of the discharge; the general appearance of the inflamed organ; and (if such were the case as very generally happens), by the presence of other catarrhal symptoms, or the prevalence of catarrhal affections generally. It is not likely to be confounded with gonorrhœal ophthalmia, on account of the mildness of the symptoms of the disease under consideration, compared with those of gonorrhœal ophthalmia, the difference in the qualities of the secretion, and the absence of severe chemosis, and extreme tumefaction of the eye-lids. It is however more difficult to lay down certain rules by which catarrhal may be distinguished from purulent ophthalmia in the adult, especially when this latter affection is very mild: purulent ophthalmia is attended with a discharge of a yellow colour and of a distinct purulent nature; the meibomian glands are not materially affected; it is capable of being readily propagated by contagion; it is not attended with an affection of the other mucous membranes; and it does not appear that atmospheric influence alone is capable of producing it; at least, if it be so, it is only in a few very rare instances: catarrhal ophthalmia is, on the contrary, attended with a discharge of a greyish colour, and

* One of the most severe, and at the same time best marked cases of catarrhal ophthalmia I ever witnessed, occurred in the person of a gentleman who was walking out one cold evening for nearly an hour, during a heavy fall of the most chilling sleet he had ever remembered. The disease commenced on the following morning, but was unattended by any affection of the other mucous membranes.

a mucous quality*; it is accompanied with great irritation of the tarsal margins; it often begins in the palpebral portion of the conjunctiva, the former disease being almost invariably confined at its commencement to the sclerotic conjunctiva; it is not propagated by contagion; it is generally connected with an affection of other mucous structures, and in many instances is much controlled by atmospheric influence. If you will carefully bear in mind these circumstances, and contrast them with those I have pointed out as belonging to other diseases of the conjunctiva, I do not think you will often be mistaken in your diagnosis of catarrhal ophthalmia.

Treatment.—It will not be necessary to enter upon the consideration of the treatment adapted to that stage of the disease (if indeed it can properly be termed a stage of catarrhal ophthalmia) when, either from the omission of remedies, or the misappropriation of them, it may have extended to other textures, and involved the deep-seated and more important structures of the eye, inasmuch as I have already spoken at some length on that subject when treating of simple acute inflammation of the conjunctiva, and besides such a state of things is of very unusual occurrence: my observations, therefore, will be directed to the management of those two conditions termed the first and second set of symptoms.

The severity of the symptoms would determine the propriety of general bleeding, and also regulate the amount of blood you might deem it adviseable to abstract; you might bleed in the arm, or take blood by cupping, either from the temples or the back of the neck, as you might judge best suited to the circumstances of the case; or the symptoms may be so exceedingly slight, and the patient so weak and delicate, that you might think it more prudent to apply merely a few leeches, or indeed not to take away any blood, either by general or local means. You will generally afford great relief by the abstraction of blood, and frequently remove the inflammation in a few days, by so commencing your treatment. It is right of course to keep the bowels perfectly open, and for this purpose you will select from among the various kinds of purgatives, such as appear to be most suitable to the various circumstances of your patient: the weak delicate subject of a relaxed habit, would probably be injured, and needlessly enfeebled, by an amount of purgative medicine, which would be inadequate to produce the slightest action on the bowels of the hardy and robust. It would be adviseable to administer at bed-time, a few grains of calomel with ten or fifteen of Dover's powder, and to direct the careful use of a pediluvium, more especially if other catarrhal symptoms be present: aware how much depends on the proper use of the pediluvium, I never recommend it, unless it is tolerably certain that the patient will be carefully and judiciously managed during and immediately after its employment, for it will occur to you that such a remedy imperfectly applied might aggravate the malady it was intended to relieve. To prevent the agglutination of the tarsal margins, and to correct the altered state of the meibomian secretion, you might order the unguentum plumbi* to be smeared along the edges of the eye-lids, two or three times a day, first removing the discharge which is apt to collect in that situation by bathing the part with warm milk and water: you would be careful to direct this ointment to be applied at bed-time, as its application will greatly contribute to your patient's comfort, and prevent that adhesion of the lids which is not only injurious but very painful. Your collyria will consist of some astringent fluid; a weak solution of alum or zinc will generally answer the purpose of relieving pain, and diminishing the discharge; they may be applied either in a warm or cold state as may be most soothing to your patient's feelings: prejudice would direct you never to apply them under such circumstances when cold, but experience will give you very different instruction, but I have previously pointed out the circumstances which would regulate your practice in this particular. It may be adviseable to use anodyne fomentations, such as a weak aqueous solution of opium, or a decoction of poppies: an extremely painful condition of the eye, or, an unusual irritability of constitution, would render such local applications desirable.

I forgot to mention that if the disease be so little severe that you do not think the removal of blood necessary, or if venesection has been practised and the inflammation be only slightly diminished, it would be right to apply a blister to the nape of the neck, or to adopt some other mode of exciting counter-irritation.

As intolerantia lucis is not one of the usual symptoms of this disease, you would not judge it necessary to exclude light from the eye altogether, but merely direct the patient to wear a green shade, and thus protect the inflamed organ from the vivid impression of its more brilliant rays; certainly no mode of protecting the eyes from

* I do not mean to deny that when catarrhal inflammation of the conjunctiva has been long continued or unusually severe, it may give rise to distinct purulent discharge.

* This ointment may be conveniently prepared by carefully rubbing half a drachm of the liq. plumbi acetatis into an ounce of well made spermaceti ointment.

light beyond this, can, in ordinary cases, be required.

Of course it will be requisite to limit the diet of the patient, in a great measure, to warm diluting beverages; no animal food or strong liquors should be allowed until the symptoms are declining, and you will find it prudent, if you desire to prevent a return of the disease, to be imperative in your request, and not to allow the full diet to be resumed too soon.

It is well known that medical men differ greatly, not only in their views of disease, but also as to their modes of treatment; and I shall illustrate this fact by reading to you one or two sentences from that part of Dr. Vetch's observations on diseases of the eye which refers to the treatment, and indeed includes nearly the whole of his remarks on the treatment of catarrhal ophthalmia. "It is a well-known fact," says he, "that the application of a powerful stimulant to a part in which inflammation has taken place, will, by carrying the excitement of the vessels beyond the action of the disease, put a stop to the further progress of the inflammation. On this principle, this form of ophthalmia yields for the most part to any strong stimulus applied to the part, such as spirits of vinegar: snuff blown into the eye has the same effect of curing this inflammation, by exciting a greater, though a temporary distention of the vessels*." If you for a moment reflect on the nature of the remedies here recommended, and at the same time consider that their use comprehends nearly the whole of the treatment advised for the cure of an acute inflammation of the eye, you will agree with me that it is not more meagre and inappropriate in means than unscientific in their application. The unguentum nigrum has recently become a favourite application, (particularly with Mr. Guthrie)† for the removal of this and many other forms of inflammation of the conjunctiva, attended with increased discharge from its surface; but I cannot recommend its use for the cure of catarrhal ophthalmia. I shall have occasion to point out to you in the course of these lectures many diseases at a certain stage of which it may be advantageously applied.

CHOLERA AT HUTTON—ITS PROPAGATION BY CONTAGION, &c.

Stokesley, 15th Nov. 1832.

Sir,

Believing, as we do, that the object of the Central Board is to obtain every possible information respecting the malady which has lately prevailed in the village of Hutton, we take the liberty of making a few remarks not directly coming under any of the heads in the printed forms sent from your Board, which, filled up, are herewith returned.

The elevation of Hutton, its open and dry situation, the general cleanliness of its inhabitants, and their not dwelling in crowded or ill-ventilated houses, would seem to have rendered the place little likely to be visited, especially so severely, by the spasmodic or Indian cholera; but in this, as in most things, human foresight may learn the futility of its prognostications—worldly wisdom the narrowness of its knowledge.

The medical profession are divided in opinion concerning contagion in cholera: we think it our duty to state our opinions on this head, not presuming to think that the mere experience of the disease at Hutton can alone be decisive. Having no theory to advocate, no preconceived notion to support, we shall simply state the facts on which we found our ideas of the contagious nature of cholera, and trust they may be deemed fair and reasonable grounds for the conclusion we have come to. It may be premised that one of the undersigned had previously been disposed to consider the cholera non-contagious; the other from having had ample opportunity of investigating the disease at Stockton, where he resides, as likewise last winter at Newcastle and its vicinity, was inclined to a contrary opinion. We shall now briefly state the facts which have produced a conformity of sentiment, and induced the conviction that the cholera *may* be conveyed by contagion; not, however, by any means denying, but, on the contrary, believing in its extension epidemically, independent of contagion.

The weaver, John Cooke, the subject of the first case, had been under medical treatment for diarrhœa previous to his departure from Newcastle, where it is a matter of notoriety that the cholera prevailed, though we understand no reports were made. J. C. reached home on the afternoon of October 2d, and within a few hours was in the collapsed stage of the disease, and fell a sacrifice to it early in the morning of the 3d. Stephen Catchesides was much with him before death, and assisted in laying out the corpse. Isabella Walton, on the 4th,

* A Practical Treatise on Diseases of the Eye. By J. Vetch, page 174.

† Medico-Chirurgical Review for July, 1832.

washed the clothes of the deceased, and William Bainbridge was much about and playing with them. Bainbridge's house adjoins Cooke's on the one side, and three of the family died; Cateheside's on the other, and four died. These houses have a common yard; and it may further be observed, that all the cases were confined to the immediate neighbourhood of them, with the exception of the above named Isabella Walton, her son-in-law, and a young married woman in the adjoining house, who lived at Enterpen, a distinct and separate part of the village, leaving the larger portion of the place entirely exempt from the disease. It may here be remarked that no communication, or almost none, took place between those residing in the immediate neighbourhood of the disease, and those at a little distance from it, except by the vicar and the undersigned*.

We deem it unnecessary to adduce further evidences in support of our opinion, since, if the above facts be considered inconclusive, we cannot perceive how contagion (employed to embrace infection) can have any existence except in those cases where inoculation may be said to afford us tangible proof. In whatever way, however, the disease is disseminated, we are willing to admit there is something inexplicable about it. There appears to be a period, wherever it prevails, when the exciting cause, be it what it may, seems to have its intensity accumulated, which after a time, depending probably on the extent, and other circumstances of the place, gradually declines, as evinced both by the number and severity of the cases.

At Hutton, from the 6th to the afternoon of the 8th of October, its virulence was at the highest; and though it is very true we had severe and fatal cases after the 8th, we certainly, on the whole, found the disease more manageable. Another circumstance it may be proper to notice, though we do not profess to account for it. Certain patients appear on the first seizure to be death-stricken, and all human efforts are fruitless. Two very marked instances of this occurred in the cases of Mary Bainbridge and Elizabeth Skelton, in both of which, in spite of every care, and of every possible exertion on our part, the disease, without a check, went rapidly on to its fatal termination. In both, grief, despondency, and fear, we may fairly state to have been powerful predisposing causes.

Let it not be supposed from this that we are inclined to advocate inattention or inactivity in any instance—far otherwise: these hopeless cases may be suspected at their outset, but cannot be positively ascertained; and, therefore, we are disposed ourselves, and would strongly urge it on our professional brethren, to employ in such cases exertions more unremitting, and attempts more varied.

The symptoms of this disease have been so often and so ably delineated, that it is needless to enlarge upon the subject; unless it be worthy of notice, that in all the cases the secretion of urine was wholly suspended. That we consider, on the whole, severe cramps rather a favourable occurrence; at least, those who fell most speedily victims, either had none, or scarcely any. It is likewise a fact that children are exempt from cramps. Aware that some of the profession consider all hopes at an end when the pulse at the wrist is imperceptible, we think it right also to state that we had four or five cases where at one period of the complaint, with the most careful examination, we could discover no pulsation, yet the patients recovered.

Previous to the appearance of cholera at Hutton, there had been a few cases of the common fever of the country; and since its subsidence, others of a more severe character have occurred—many fatal; of which Jane Cooke, who had the cholera mildly, was one. But one further remark, previous to entering on the treatment; and this we make, not from any idea that the circumstance is at all connected with the disease, or even (as far as we could ascertain) a predisposing cause. In almost every case, adults as well as children passed the *vermes teretes* in the dejections or by vomiting; and from observation among others in the village, variously affected, but not seized by the cholera, these were voided if cathartics were administered. As regards the treatment adopted at Hutton, we have little to remark. Blood-letting in no case seemed to prove of much benefit, and in some certainly hurried on the collapse. Emetics, either of common salt or mustard, on the approach of the collapse, or when the characteristic diarrhœa had continued

* By a return which accompanies this paper it appears that all the persons alluded to in the above paragraph became successively affected with cholera.—E. G.

for some time without vomiting, but a pain or sensation of uneasiness at stomach or bowels, with (in some cases) nausea, we found very useful. Calomel, both in large and small doses, with or without a small portion of opium, decidedly answered our expectations best. It has been said we should be cautious in the administration of large doses of powerful medicines, as the assimilating functions, being suspended or very greatly lessened, much is to be feared from their accumulated effects when re-action takes place: in so far as it regards calomel, this is, we believe, a needless apprehension; as, in no one instance, even where very large doses had been ofttimes repeated, was there the slightest degree of what is commonly stiled mercurial action. In several instances the croton-oil was used, and, we believe, with advantage in many. In one case, where the patient had been for hours previously considered to be in a state precluding all hope, two drops of the oil were given, and an hour after, another; shortly after which, being left for a few minutes alone, he got out of bed, used the night-chair, and passed a full, good, feculent dejection, though at this same time no pulsation was perceptible at the wrist, and he had, through the preceding night, been delirious. His habits had been for years (especially for the last three months) intemperate in the extreme. A few hours after this appearance of improvement, jactitation and restlessness came on, and he sunk: yet surely in this case we are entitled to consider the oil to have acted beneficially. Astringent enemata, and also sinapisms, were freely had recourse to, and from which doubtless some good was obtained. Stimulants did not afford us any satisfaction, and they were very little employed, except in those cases which occurred in old age.

Ere we close this report, we cannot avoid declaring our unqualified opinion that vast injury has accrued by the crude suggestions and the absurd specifics which the quacks, both in and out of the profession, were daily, by means of the diurnal press, foisting on the public: but while we sincerely lament the mischief done by these, we entertain a firm hope that the Central Board may be enabled to collect such a mass of experience from, unhappily, the numerous local boards in correspondence with them, as shall afford a very desirable acquisition to our knowledge on this subject when laid before the public. If we may be allowed to suggest, there are certain desiderata which the Central Board, we conceive, have the only, or at least the readiest means, by their connexion with government, of having effectuated—viz. if, as we are disposed to believe the disease, under certain circumstances, to be contagious, to have an efficient power established, with sufficient means at disposal for the cleansing and purifying the habitations that may be visited by the malady; for preventing, as far as possible, more than the necessary intercourse with the sick, and the speedy interment, in deep graves, of the unfortunate victims;—but, above all, for the destruction of the clothes, &c. of any one who may have died of it, since it is a fact which it is not for us to explain, that, until the cholera evinces itself in a place by a more than usual number of deaths, there are numbers will give no credit to its existence; and, ignorant that it mostly proves a positive loss to the profession, declare the rumour of its presence is only to serve the private ends of the practitioners.

In conclusion, we have to acknowledge our high sense of the conduct of the Rev. R. J. Barlow, whose unremitting exertions, and ready and constant attendance on the sick, are beyond all praise, and without whose aid we should have had much difficulty and prejudice to contend with, and our endeavours must have been still more unsatisfactory: delicacy forbids us to say more, while justice condemns us for so inadequately and unworthily noticing his strenuous and laudable efforts.

We have the honour to subscribe ourselves, sir,

Your very humble and
obedient servants,
(Signed) R. H. KEENLYSIDE, M.D.
J. ALLARDICE, Surgeon.

To W. Maclean, Esq. Secretary to the Central Board of Health.

PERFORATION OF THE HEART.

To the Editor of the Medical Gazette.

SIR,

IT has been the subject of censure that young practitioners should betray a fondness for the observation of cases,

which, from their rarity, seldom require medical treatment; and this censure would no doubt be merited, if they neglected to acquire that knowledge which is only more useful, inasmuch as its application is more frequently called for. And it is questionable if a more extensive cultivation of morbid anatomy will not prove the comparative frequency of those pathological conditions which are now considered as of rare occurrence.

Oct. 9, 1831.—At 8 A.M. I was requested to visit Richard Abraham, ætat. 63. On the previous day he had followed his usual occupation of breaking stones on the road, but on his return in the evening he complained of indisposition, and in the course of the night suffered from a fixed pain in the left side of the chest, which extended across the sternum and through the right side, but still he referred to the left side as the seat of this pain.

I found him lying on his back, his head and shoulders being particularly low, the surface of the body was cool, the pulse regular and natural, beating 84 in a minute, the bowels acting properly, no thirst, the tongue rather coated in its middle, respiration perfectly free and natural, no cough, the pain not increased either by attempting to cough or by inspiring deeply, but slightly if he turned on the left side, no lividity or other change in the appearance of the countenance.

Suspecting that an inflammation of the chest, from previous exposure to cold, was about to declare itself, I ordered the position of the patient to be altered by placing pillows under the shoulders, the surface to be kept moderately warm, and some warm gruel to be administered with two calomel and colocynth pills; promising soon to make a second visit, to determine on the necessity of bleeding and such other measures as after reaction should be established might seem called for.

In about an hour from this time he complained of sickness; he was raised in bed, retched, appeared faint, and died without further struggle or complaint.

On the following morning I examined the body with the kind assistance of Dr. Burrows, and found the pericardium distended with full two pounds of dark blood, which was partly fluid and partly coagulated. The heart was found to be perforated near its apex so as readily to admit the little finger into the left ventricle; the edges of this perforation presented the irregular appearance of a muscular part forcibly torn asunder. The other thoracic, together with the abdominal viscera, were beautifully healthy—not the slightest vestige of present or past disease could be traced. I regret that the bloodvessels were not minutely examined, but in the ascending aorta, not far from the heart, I found two portions of ossification, which did not however involve any thing approaching a circular portion of the vessel. This man had suffered frequently from chronic rheumatism, and had complained of occasional pain in the chest, attended with palpitation.

Excepting the rent in the ventricle, I observed nothing morbid in the appearance of the heart, which is placed in Mr. Richard Smith's Museum at the Bristol Infirmary, but to be quite sure of this I wrote to Dr. Richard, from whose kind reply I quote the following.

"* * * I perceived, of course, the perforation of the left ventricle. The muscular parietes appear otherwise to be in a sound state. The only morbid phenomenon which is discoverable is a plate of bone, being an ossified portion of the internal membrane, including one of the aortic valves. The heart certainly appears large, particularly the left ventricle, but I am not sure that the enlargement is to a degree that can clearly be said to constitute disease."

If I have not occupied too much of your valuable space I will beg permission to view this case in reference to physiology.

The importance of morbid anatomy as a branch of pathology is most happily appreciated, but its subserviency to physiological knowledge is not sufficiently estimated.

The dark colour of the blood when not circulating in the arteries, was, of course, familiar before the occurrence of the above case, yet objects, which from their familiarity with our senses, too frequently pass unheeded, will sometimes arrest attention in a peculiarly forcible manner, and such was the case with me in this instance.

Here was a mass of blood in a shut sac, covering and investing the heart, which had escaped from the left ventricle, the immediate receptacle for the purified blood from the lungs, and yet it was as apparently venous as though it had gone the round of the circulation. It is still

further observed by Dr. Badham, in one of your late numbers, that if the current in a living artery be only interrupted by pressure on the vessel, that the blood so obstructed assumes the venous colour. This Dr. Prichard remarks, in the letter already alluded to, "is a curious circumstance, and difficult to be reconciled with the prevailing theory of the changes which the blood undergoes in respiration," whether we regard that of oxygenation, or the more satisfactory hypothesis of simple decarbonization.

I do not pretend to the accuracy necessary to a satisfactory induction from physiological phenomena, but I regard this as a delightful and promising subject for the attention of those who are competent to its investigation, and to such I would suggest, that experimentalists have relied too exclusively on the fascinating but abstract laws of chemistry. They have viewed arterial, as only chemically differing from venous blood, without examining what power may be exercised by the living vessels, which are thus too often degraded into mere tubes or hydrostatic instruments.

I have the honour to be, sir,
Your obedient servant,
JAMES HURD.

Cleeve Cottage, Yatton,
Near Bristol, Oct. 29, 1832.

CHLORINE AND THE ALKALOIDS.

To the Editor of the Medical Gazette.

SIR,

In the perusal of your excellent journal, I have observed some papers on that part of vegetable chemistry which concerns the alkaloids, and accordingly I have sent you an account of a few curious *facts* which I have observed in my experiments on them, and which you may deem worthy of insertion.

If chlorine be passed through sulphate of quinine suspended in water, it will soon be dissolved; and if ammonia be added to this solution, a beautiful green colour will pervade it, which in the course of a day or two will fall to the bottom of the vessel in the form of a precipitate. I likewise observed that potassa or soda being added, produced a light brown colour, which presently became almost black. The carbonated alkalies do not produce this effect. Chlorine passed through morphia suspended in water, and ammonia being added, when it is dissolved, produces a dark brown colour. In some instances this will answer as a test for the above substances, as it will detect with ease the hundredth part of a grain, and as chlorine produces no effect on any other of the alkaloids that I have as yet examined.—I am, sir,

Your very obedient servant,
ALEX. ROPER.

Guy's Hospital, Nov. 30, 1832.

CASE OF SOLUTION AND PERFORATION OF THE COATS OF THE STOMACH AFTER DEATH:

With Remarks.

To the Editor of the Medical Gazette.

SIR,

C. L. aged 2 years, a delicate looking child, of a scrofulous habit, has been declining in health for a considerable time. At first, his complaints were cough, deficiency of appetite, and great general debility, followed by loss of power in the inferior extremities. At the time medical advice was obtained, which was only ten days before death, he presented the following symptoms:—quick pulse, hot skin, a severe cough, attended with a copious muco-purulent expectoration and hurried respiration, arising evidently from the presence of tubercles in the lungs. The head also exhibited marks of congestion or subacute inflammation; and before the fatal termination, coma, dilated pupil, and other symptoms of effusion in the brain, came on. The usual treatment was employed:—leeches and blisters to the head, calomel, &c.

Sectio Cadaveris, thirty-six hours after death.—Body much emaciated. In the head, marks of congestion were observed: the vessels of the pia mater and those on the surface of the brain were loaded. The ventricles contained a little more than a drachm of serum. On slicing the substance of the brain, more red points than usual were seen. In the thorax, there were found considerable adhesions of the pleura, and a small quantity of serum in the cavities. A very considerable portion of both

lungs was studded with tubercles in an early stage of progress, which in some parts were coalesced together in large clusters. The divisions of the bronchiæ were filled with thick yellow mucus of a purulent appearance, and the internal membrane was reddened. Upon opening the *abdomen*, a large aperture was found in the larger extremity of the stomach. The edges of the opening were irregular, ragged, and very much softened; and the mucous membrane in some parts at the edge of the opening was almost in a pulpy state. There was not the least appearance of the deposition of lymph, any thickening or mark of inflammation around the edges of the perforation. In all other parts, the coats of the stomach were quite healthy, and of their natural appearance. The size of the opening was large enough to permit a small orange to pass through it. The stomach contained a little fluid like gruel, which had been taken a short time before death; and some of the contents had escaped at the opening into the cavity of the abdomen. The parts on which the fluid which had been poured out of the stomach was lying, were perfectly healthy and natural in appearance, and did not exhibit the least redness, or any sign of inflammation. There was no other morbid appearance in any of the abdominal viscera, except some of the mesenteric glands.

John Hunter was the first who took notice of the circumstance, that the stomach is occasionally found perforated on opening a body after death, although no symptom indicating any disease in that organ had existed during life. In his opinion, this solution and perforation of the coats of the stomach is owing to the solvent power of the gastric juice, acting on the parts after death, and although this explanation has not appeared satisfactory to some, yet it seems more probable than any other which has been advanced. He considered that the vital principle enables animal matter to resist the powers of digestion, as well as fermentation, &c.; but the moment the living principle is lost, it becomes subject to the digestive powers of the gastric juice. Perhaps one of the most powerful arguments against this explanation is the rarity of the occurrence in question; but it appears to me there is a combination of circumstances necessary for its production, all of which are seldom present, which satisfactorily accounts for the appearance being so rarely observed.

The fluid which is secreted by the stomach when empty, differs materially from that secreted when it contains aliment: indeed, the presence of food seems to be a necessary stimulus for the secretion of gastric juice of proper digestive powers. The gastric juice collected from the stomach of an animal fasting, is a transparent ropy fluid, without any alkaline or acid qualities. During the process of digestion, on the contrary, it possesses acid properties, depending on the presence of free muriatic acid, as was proved by Dr. Prout; and Tiedemann and Gmelin have remarked, that the secretion of acid begins as soon as the stomach receives the stimulus of food, or any foreign body. This effect is occasioned, for example, by the presence of flint, stones, or other indigestible matters; but it is produced in a still more remarkable degree by substances of a stimulating nature.

The liquid found in the stomach of an animal after long fasting, consists of the fluid secreted by that organ, as well as the mucus from the pharynx and œsophagus and the saliva, and in all probability does not possess solvent powers in a very remarkable degree; and I think we may thus explain the discrepant results obtained by different physiologists.

In the experiments of Spallanzani, alimentary matter was digested out of the body by the action of the gastric juice, when due precaution was taken to preserve the proper temperature. He obtained the fluid used in his experiments by means of a sponge introduced into the stomach, the presence of which is quite a sufficient stimulus to cause a secretion of gastric juice of full activity. Mr. Carswell, also, in a paper read before the Royal Academy of Medicine of Paris, states, that having procured gastric juice from the stomachs of living animals, he put some of it into the intestines, urinary bladders, and stomachs of dead animals, and found in every instance softening or perforation to take place. He likewise mentions that he produced perforations in the coats of the stomachs of rabbits at will. They were killed after eating, and according to the time which had elapsed after death, upon inspection the coats of the stomach were softened or completely perforated. In the experiments of Dr. Wilson Philip

upon rabbits, he found, in many cases, the great arch of the stomach dissolved to a considerable extent and perforated, especially when the animal had been killed a short time after eating fully, and when the body had been left for some time after death before it was examined. MM. Leuret and Lassaigne found the gastric juice of a duck, obtained by means of a sponge, capable of digesting bread crumbs, and that flesh was quickly softened and deprived of weight by the action of the gastric juice of a dog. The experiments made in the case of the lad who had a fistulous opening into the stomach, mentioned in the American Medical Recorder, January 1826, are also quite conclusive as to the capability of the gastric juice to effect digestion out of the body.

In the experiments of M. de Montègre, on the contrary, the gastric juice was incapable of digesting alimentary matter out of the body. This physiologist possessed the power of being able to vomit at pleasure the fluid which had collected in his stomach after fasting, and with this he performed his experiments. Now it is not at all surprising that he did not obtain the same results as the preceding authors have done, because the fluid he used was that contained in the stomach when that organ was not under the stimulus of food, or any other substance, which, as has been before stated, is totally different from that secreted by it after a meal, and is quite inadequate to effect digestion.

That the perforation occurs after death is, I conceive, quite certain, for, if that were not the case, there would most undoubtedly be marks of violent inflammation in the abdomen discovered on dissection, owing to the escape of the contents of the stomach into that cavity. Indeed, it is evidently totally distinct from any action going on during life, as there is no thickening around the edges of the opening, nothing like the deposition of lymph, no increased redness, nor any traces of inflammation whatever.

It might *à priori* have been supposed, that this perforation would have been most likely to happen when the stomach contained no food, as the gastric juice would then be applied more directly to its coats, but the reason why this is not the case is evident from what has been said. I am not aware, indeed, that the appearance in question has ever been observed in cases where the stomach contained no food or foreign body; and Dr. Gairdner states, that all the cases of erosion and perforation which fell under his notice, contained some portion of alimentary matter.

This perforation, of course, is not likely to be met with in affections of the stomach, because a healthy gastric juice is not secreted. Whether, however, it is possible that, from a disease of the stomach, a fluid may ever be secreted possessing greater solvent powers than ordinary gastric juice, is a question which it would be interesting to determine.

As it is now satisfactorily proved that the gastric juice is capable of digesting animal food out of the body, we must admit, that if the stomach, at the moment of death, contains some of this fluid of active qualities, it will be capable of digesting that organ itself, or any other with which it may come in contact. Hence, if a man in good health is killed suddenly after having taken food, the stomach becomes subject to the same laws as other dead animal matter, as soon as life is extinct, and is therefore as much under the influence of the gastric juice; and as the temperature of the internal parts of the body is kept up for some time after death, the digestion of the coats of the stomach is an occurrence which we should naturally expect to find. Accordingly, the cases mentioned by John Hunter were individuals who were killed under these circumstances. It is not, however, in cases of sudden death alone that this appearance has been observed; for instances are related by authors of its having presented itself in persons who have been ill a considerable time—as in the case of the child mentioned above: but then it is probable that, in these examples, the stomach participated but little in the disease, and was not incapable of secreting gastric juice of active properties. Still, however, we are not likely to meet with this perforation after death in common cases, because the low state to which the vital powers are generally reduced, renders the stomach incapable of secreting healthy gastric juice. Cases of capital punishment might be considered favourable for the production of perforation of the stomach; and as the bodies of those who suffer are generally examined, it might perhaps be expected they would afford numerous examples of it; and, in fact, one of the cases which occurred to John

Hunter was that of a man who had been hanged: but I apprehend the state of mind under which the culprit must labour is quite a sufficient cause to account for the rarity of the occurrence under these circumstances; for the effects of mental emotion on secreting organs are well known.

From the remarks which have been made, we may conclude that, in order that this perforation of the stomach may occur, it is requisite, in the first place, that food should be taken a short time before death; that death should take place suddenly, while the stomach is in a healthy state; or, at least, that if it occur from a protracted disease, there be no affection of that organ which shall prevent a secretion of active gastric juice; and that the temperature of the body be not materially reduced previous to death, nor suffered to decrease too rapidly after death.

The necessity of attending to this appearance, in connexion with medico-legal inquiries, is of the highest importance, as it is in cases of sudden death, where suspicion of poisoning might be excited, that it is most likely to be observed.

[The name of the author of this interesting paper has not been transmitted to us: we suspect it was omitted in the hurry of transcription.—E. G.]

ANALYSES & NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

Epidemia Variolosa, del 1829, *in Torino*, &c. Per T. D. GRIVA. Or,

"*An Account of the Variolous Epidemic which prevailed in the continental dominions of his Sardinian Majesty during the years* 1828, 29, *and* 30." By T. D. GRIVA. Turin, 1831. Pages 250.

WE have been much gratified by the perusal of Dr. Griva's work, which is published by authority of the Minister of the Interior. It is drawn up with singular clearness, and is quite a model for similar reports. Indeed, we would strongly recommend it to the serious attention (and imitation) of the members of our own National Vaccine Board, whose official communications have hitherto been distinguished by a kind of epigrammatic brevity*. Here we have a goodly volume of 250 pages, which, mixed with some trash, contains a vast fund of very curious and instructive matter. The reports of the Italian vaccinators are particularly interesting, and testify an acquaintance with their subject which is highly creditable to them. Our limits forbid any attempt at a formal analysis of the contents of this volume. We can only hope to convey to our readers some general impression of the mode in which *Italian* physicians record the medical occurrences of their time.

The epidemic which it is the object of this volume to describe had previously devastated other parts of the world. It appeared in Sweden in 1824; in London in 1825; in Philadelphia in 1826; in various departments of France in 1826; in Marseilles in 1827; at Nice in 1828; from whence it spread to Turin and Genoa, ravaging the continental dominions of his Sardinian Majesty in 1829. A tabular view is given of the results of the epidemic in the 40 provinces composing that kingdom, of which the following is an abstract:—

Total population (in round numbers)	3,440,000
Annual number of births	103,000
Numbers attacked by small-pox in the epidemic of 1829-30	35,146
Total deaths by small-pox out of that number	6,052

This rate of mortality is low, being only 17 per cent. The disease appears to have prevailed *chiefly* among the juvenile portion of the population, though adults came in for a share of it. Turin suffered severely. Between March 1829 and March 1830, the capital (containing a population of 121,000) lost 785 persons by small-pox, of whom 528 died in three months (July, August, and September.) The following statements (at page 56) are very interesting:—

In Turin, 156 persons took small-pox a second time, while 57 only took it after vaccination. Of the former there died 9, and of the latter 5, but these 5 had only been vaccinated a few days, and the vaccination had not completed its course. The proportion of those who took small-pox after vaccination in the provinces, is not given.

* We have never met with the National Vaccine Report for the present year. Has it ever been published, or circulated?

The benefits of vaccination are placed in a very striking point of view in several parts of the work. The annual average of the vaccinated had been 52,000, but such was the dread of the disease, and such the confidence reposed by all ranks in the efficacy of vaccination, that in 1829, (during the prevalence of the epidemic) the total number of vaccinations amounted to 81,426, being in the proportion of 79 to 100 of the births.

The efforts of the government for the encouragement of vaccination were incessant. Notices were published in the newspapers recommending vaccination, and instructing persons how to proceed. Circulars were sent to the provincial administrations, and to the bishops of the several dioceses, recommending exhortations from the pulpit in favour of vaccination. The national schools were directed to insist upon certificates of vaccination from all pupils, and returns were ordered from all district vaccinators. The results of such strenuous exertions were highly satisfactory, and the mortality, though great, fell very short of what might have been calculated upon.

A large portion of Dr. Griva's book is devoted to a detail of the labours of the Piedmontese vaccinators. We can only touch upon a few of the many interesting topics suggested in their reports. At an early period of the epidemic, it was proposed to revert to *primitive* lymph, and various efforts were made in the Alpine pastures to find it. Three packets of the genuine lymph (fresh from the cow) were received in June and July. Sixteen persons were vaccinated from this source, which succeeded in four cases only. "In none of these was it possible to trace any difference whatever between the course of the *primitive* and of *humanized* lymph," (page 104.)

We read, (page 64) that under ordinary circumstances, the proportion of failures to successful vaccinations is as 1 to 10, or 12. This would appear to depend, in a considerable degree, upon certain conditions of the atmosphere, for as the season advanced, such failures became more numerous. Thus in February they were as 1 in 10; in April as 1 in 7; in June as 1 in 5; in August 49 failed out of 153, being in the proportion of 1 in 3.

Much research is displayed in the 11th chapter, with a view of explaining this singular fact. Three explanations of it are offered. 1. Alterations in the quality of the lymph itself, effected either *spontaneously*, or by the agency of heat, moisture, light, and electricity. 2. Conditions of the atmosphere operating by impediment to cutaneous absorption. 3. Idiosyncracies, or *anti-contagious* constitutions. It was observed by four vaccinators, that children who resisted vaccination, resisted equally variolous *infection*, a statement which we have had frequent opportunities of verifying. The repetition of vaccination under these circumstances, at distant intervals, in the belief that such unsusceptibility is only temporary, is strongly and most properly recommended, (page 157.)

One great object with the author is to prove (and this he does to our entire satisfaction) that one good *regular* pustule is just as effectual a preservative against small-pox as a dozen; and, further, that constitutional symptoms are not requisite to ensure ultimate security.

We must here take our leave of Dr. Griva and the Italian vaccinators. Their zeal and science are alike commendable; and we trust that the example here set of a *national* contribution to pathology will not be lost upon the practitioners of this country.

The Elements of Anatomy. By Jones Quain, B.M. Professor of Anatomy and Physiology in the University of London. Second Edition, revised and corrected. Taylor, 1832. Pages 812.

It would be mere affectation on the part of a reviewer to say that he had read much of a work like that before us. It is not intended to be *read*, but to be studied; and all that we can pretend to have done by it is to have looked at the chief points of its arrangement, observed the general style of the writer, and examined some individual points, to ascertain the degree of precision and clearness which he has given to his descriptions. Another portion of such works, too, to which we always give heed, is the table of contents and index; for a book may be a very good book as regards its general interior, and yet be defective for want of easy references, just as a country may be beautiful, and yet be inaccessible for want of roads and finger-posts to direct us on our way. Now applying these tests to Dr. Quain's

Anatomy, we find the results to be very satisfactory. The arrangement is good, and the language perspicuous—equally free from the vice of being too general, or descending into over-minute details, such as are sometimes to be found in works of this description, whose authors seem to have mistaken refinement and prolixity for precision and completeness of description. The various parts are considered according to the *descriptive*, *analytical*, *and historical* methods, and the manner in which the task is executed appears to us to constitute a highly useful and scientific elementary system of anatomy.

Lectures on Anatomy, interspersed with Practical Remarks. Vols. I. II. III. IV. By B. B. Cooper, F.R.S. Surgeon to Guy's Hospital, Lecturer on Anatomy, &c. Longman, 1831-2.

We have before alluded to this work while yet in progress, and have now to recommend it to our readers in its completed state. We decidedly disapprove of the method of publishing works in this manner: people do not like to obtain a system of any thing volume by volume: they like, and very naturally, to know the value of the entire article before they make the purchase. Now that they have it all before them, the many good points in Mr. Cooper's lectures will be better appreciated than they can have been heretofore. The plan of the work is different from that of most others which have lately appeared, and comes nearer to that of the Bells, now many years before the public. A great deal of theoretical and practical detail is mixed up with it, and in fact it is not a mere system of descriptive or general anatomy, but of anatomy in relation to physiology and surgery. Much of the dryness unavoidably connected with bald anatomical description is thus got rid of, and the consequence is, that it is far more *readable* than works on such subjects usually are. In keeping it within four thin volumes, Mr. Cooper has acted judiciously, and we perceive that he has also kept the price very moderate under the circumstances. It is handsomely "got up."

MEDICAL GAZETTE.

Saturday, December 8, 1832.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri: potestas modo veniendi in publicum sit, dicendi periculum non recuso."
Cicero.

THE LATE PROFESSOR SCARPA.

It is our custom, as our readers know, to preserve short biographical memoirs of eminent and recently deceased members of our profession: no apology, then, we conceive, is needed for introducing the following succinct account of the late illustrious professor of Pavia.

Antonio Scarpa was born at Friuli, in the year 1745. His family was obscure and humble. It was through the assistance afforded him by a distant relative, that he was enabled to pursue his early studies, but the death of his benefactor soon left him altogether dependent upon his own resources. Whatever may be the feeling of interest which the contemplation of the difficulties of rising genius usually inspires, in the present case facts are wanting by which such a feeling might be gratified: we only know that Scarpa "bated no jot of heart nor hope;" that he clung the firmer to the profession he had chosen, in proportion to the struggles which he saw it would be incumbent on him to make; and that in the proud consciousness of his powers, he persevered with an ardour which was soon crowned with the most encouraging success. His first work, a Treatise on the Structural Anatomy of the *Fenestra Rotunda*, was written at an early age, and excited general attention: it was followed up in a few years by the able Disquisitions on the Senses of Hearing and Smell; and the author was at once raised to the first rank among anatomists. He presently after published a series of memoirs on the

ganglions and plexuses, distinguished by the number of new facts and original views which they contained.

But it was his great work on the Nerves of the Heart which first conferred on him an European celebrity The anatomy of the heart, particularly as regarded its nerves, had been from the earliest period in an unsettled condition: the most contradictory opinions prevailed—the boldest assertions were hazarded; and even as late as the year 1792, a German anatomist, Behrends, of Mentz*, had the hardihood to publish, in the form of a dissertation, "*Cor nervis carere*," and to argue that the heart was a *stupidum et insensile viscus*. Scarpa would endure it no longer: he determined to set the question at rest, and in the course of a few months produced his magnificent folio, the *Tabulæ Neurologicæ*, which he dedicated, with a brief inscription, to the Royal Society of London. This undertaking cost him an infinity of pains, and was, in fact, composed in the short intervals of leisure which the duties of his professorship (for he was now a professor in the University of Pavia) allowed him. One is surprised in looking into the work at the immense industry which, under such circumstances, must have been requisite to effect it, but not so at the enthusiasm with which it was every where received.

Treatise after treatise now came from his pen, and among them the commentary on the intimate Structure of the Bones. Baxhmer, indeed, had the priority in attempting to shew the cellular structure of the bones, but he left much for Scarpa to do. Our indefatigable professor made new sections, employed fresh processes, and availed himself of others which were presented to him in the relics of an ancient cemetery with which time had long been busy. These, together with his drawings, and the admirable engravings of Anderloni, enabled him to put forth a volume scarcely less valuable than any he had yet produced.

High as was the talent of Scarpa as an anatomist, perhaps his abilities as an artist were equally so. Those who have seen the original drawings of the nerves of the heart, which he executed with his own hand, bear witness to how little remained for the engraver to do. Yet Anderloni had a difficult task to accomplish: he saw the necessity of giving much more relief than had ever been done before to the parts which he had to represent; and he determined, by the aid of black grounds, to bring out all the details and foreshortenings, in a superior manner. It was an era in descriptive anatomy. Anderloni succeeded to perfection in his design, and thenceforth worked after nature. All the subsequent productions of Scarpa were illustrated by the same artist; and it may well be conceived what a relief was thus afforded to the professor, most of whose nights used to be exclusively devoted to the labours of the pencil.

The Essay on the chief Diseases of the Eyes made its appearance in the first year of the present century: it has gone through several (at least five) editions in the original, and has been translated into almost every language of Europe. It was in this work that Scarpa so successfully advocated the propriety of depression in cataract—an operation which he rescued from disuse, if not oblivion. A method, also, it deserves to be mentioned, of operating for artificial pupil, which he proposed about the same time, he presently after abandoned, in consequence of being convinced of the superiority of that of M. Maunoir.

When the Parisian Society of Medicine proposed to have the question de-

* M. Carron de Villards, to whom we are indebted for many particulars in the text, gives the credit of the dissertation to an *English* anatomist: had he consulted Scarpa's preface, he would have found the fact to be as we state it.

termined relative to the operation for aneurism, the professor of Pavia did not disdain to enter the lists: he immediately commenced a series of experiments concerning the ligature of arteries, the result of which he published under the title of Reflections and Observations on Aneurism. It is well known that he gave the preference to a peculiar form of pressure for procuring obliteration; and in operating for aneurism, that he confined himself to Anel's process, which has been improperly confounded with that of John Hunter. In Italy, it is said that the process in question has been crowned with such brilliant success, that malignity alone would suggest a doubt of its excellence. The failures have been attributed to neglect of some of the fundamental precepts, or to the omission of certain indispensable precautions. In his memoir on Temporary Ligature of the Arteries, and in his Letters to Vacca-Berlinghieri on the same subject, Scarpa enters into the fullest detail of proofs to establish these facts.

About this time it was that, France and Italy being now under one sceptre, it was contemplated to naturalize reciprocally the most valuable productions of each country. Baron Heurteloup (father, we believe, of the celebrated lithotritist of that name) proposed to undertake a French edition of Scarpa's work on Aneurism: the Italian professor gladly consented, and offered the use of the copperplates in his possession. But M. Delpech, who was either naturally more prompt, or less burthened with business at the time than M. Heurteloup, and unacquainted with the design of that gentleman, unexpectedly produced a translation of the work, and had the plates copied and reduced by a French artist. The project of M. Heurteloup was in consequence dropped.

We need not dwell upon the other well known works of Scarpa. In 1809 appeared the splendid folio on Hernia; and it may suffice to say of it, that in every line is displayed the hand of a master. Not only have we here a clear account of the mechanism on which each kind of hernia depends, but a lucid arrangement of the several dispositions of the ring, the spermatic cord, the epigastric, crural, and obturator arteries: there are also rules for practice laid down in it, which leave little to be desired by the operator. Subsequent editions have incorporated several collateral memoirs by the professor; and a Supplement to the latest contains his researches concerning Hernia of the Perineum.

The operation of lithotomy by the recto-vesical method, which was adopted and defended with warmth by some of the most eminent Italian surgeons — among others by Vacca-Berlinghieri and Brabantini, gave rise to a brisk controversy, in which Scarpa distinguished himself, by proving that in every case the perineal or lateral method ought to be preferred. Truth, however, compels us to add, that the professor did not spare any exaggeration that occurred to him, in order to set in the strongest light the dangers which he thought might arise — those, for example, of the spermatic cords. The controversy was cleverly conducted by various adversaries; but the exactness of his details, and the depth and force of his objections, procured for Scarpa a decided superiority: nor have all the successes of Giorgi of Imola been since able to reinstate recto-vesical lithotomy in its once popular condition.

With respect to the professor's own mode of performing the operation, it may be mentioned that he employed an instrument which was a modification of the cutting gorget of Hawkins, one devised for the purpose of making an oblique incision, and at the same time avoiding the branch of the pudic artery which runs along the ischium; and this is the in-

strument which has been employed in almost all the cases of lithotomy which have occurred in Italy within the last ten years. Scarpa, however, never insisted upon his friends or pupils using his gorget: Professor Cairoli, one of his chief favourites, and now his successor, has operated more than once in his presence with the knife of Monro.

Hydrocele was a malady which engaged much of Scarpa's attention; and his work on Hydrocele of the Spermatic Cord will be found to embrace every essential in the diagnosis of the disorder.

Deformities, also, were a favourite subject with him. One of his earliest, and one of his latest, memoirs were devoted to the management of such affections: in the first of these, by directing attention to the anatomical relations of the tarsus and metatarsus in clubfoot, he much simplified the method of treatment; and in the last, he has shown that most deformities of the knee may be cured by patience, time, and proper bandaging. It would be needless to particularize a variety of other papers which he published from time to time, such as those on Aneurism by Anastomosis, Nævi Materni, or his memoirs on Scirrhus and Cancer: they are well known to every practitioner who is familiar with the medical literature of the continent.

Scarpa was a member of the Italian Institute, a foreign associate of the Academy of Sciences of Paris, and a fellow of the Royal Society of London; he was a chevalier of the Legion of Honour, and of the Imperial Order of Leopold; he might also have had, like his colleague Moscati, a senatorial robe, had it not been for his avowed attachment to the house of Austria. When the professors of the University of Pavia threw themselves at the feet of the conqueror of Marengo, Scarpa alone was absent; but it was observed that Buonaparte did not resent this open neglect of homage. By the house of Austria, indeed, his talents as well as his loyalty seem to have been duly valued. When one of the first wives of the present Emperor was attacked with scirrhus of the uterus, a flag of truce (for it was war time) was sent to demand the services of Scarpa. The surgeon of Italy crossed the Tyrol occupied as it was by the two hostile armies: the French outposts put him into the hands of the Austrians; and a similar formality was observed on his return.

To an enthusiastic love of his profession, Scarpa united an exquisite taste for the fine arts, and he was the possessor of a noble collection of paintings by the Italian masters. The museum of Pavia also owes to him much of its valuable contents.

In person he was tall, his figure graceful, and to the last, notwithstanding his great age, perfectly erect. In his manners, he was gentlemanly and amiable.

He spoke several languages, but the Latin he decidedly preferred. Simple in his mode of living, he had few wants to gratify, and he is understood to have died in possession of a large fortune. Yet the failure of his sight, amounting, we believe, in his latter years to total blindness, must have been a great drawback upon his felicity,—though, as in the case of Huber, this only seemed to redouble his industry, and to stimulate him to employ the eyes of others. The death, too, a few years ago, of Professor Jacopi, his especial pupil and protegé, at the early age of 32, afflicted him severely: he felt his loss as that of an only son.

No man was better acquainted with the actual state of the profession than Scarpa. In the circle of his friends and favoured pupils, he used to discuss freely every alleged improvement in surgery. Only a few months before his death he brought out the third volume

of his *Opuscoli di Chirurgia*, in which may be seen his admirable letter to Weber on the ganglions.

Perhaps, after all, it may be said that the works of Scarpa are more useful and exact than they are original: if by original be meant fanciful, we fully concur in that opinion: utility, positive usefulness, was the great end and aim of all his labours. In this and in his prodigious activity are his distinguishing characteristics to be found: in the latter attribute he had probably no rival in modern times except Cuvier: both these extraordinary men seem to have been ever urged by an irresistible necessity of working, and both were perhaps as surprising for the multiplicity of their researches, as for their perfect freedom from mere hypothesis. Scarpa was the author of no system—no theory that had its supporters, or ever gave rise to a revolution in science: the sciences, indeed, with which he was conversant afforded him little scope for this: but what he did accomplish had what was real in it, and shews that he was worth a whole host of speculators.

The school of Pavia, it is natural to suppose, has suffered an irreparable loss in Scarpa: even during the most active period of her great professor's career, owing to a variety of circumstances chiefly political, and affecting the state generally, this ancient seat of learning has not flourished; and in spite of the longing lingering hope still, it would seem, entertained by some of her alumni, it is to be feared she must sink ere long irrecoverably. Above ten years ago, John Bell, in the course of his Italian tour, of which we have so interesting an account in his posthumous Observations, visited Pavia, and conversed with Scarpa. It is tantalizing not to have the particulars of this interview; but as the following passage apprizes us of what were *then* the hopes of this once famous place, we give it at length, leaving the reader to draw his own inference as to what they must *now* be, now that their great light is extinguished.

"The University of Pavia is supposed to have existed as early as the year 794, having owed its first establishment to Charlemagne. It is amazing how soon a college may rise to distinction, and in how short a period it may fall into decay. Only thirty years since, Pavia was the first school for law and physic. This may be said to be the sort of body politic which the soonest rises and soonest perishes, since its fame often depends upon the life of *one man*, and dies with him. Perhaps Pavia herself may shortly give proof of the truth of this observation. I have reason to believe that she *may* again in no long period rise to her former celebrity. Such, at least, is the language held by the scientific men of this city with whom I enjoyed a short conversation while in the company of the venerable and distinguished man (Scarpa) who has such claims to admiration, not only from his brethren of the same profession, but from all who value science: nor shall I easily forget the feeling of gratification which my interview with him left on my mind*."

TRIAL FOR MANSLAUGHTER.

Mrs. Spiller, against whom a Coroner's Jury found a verdict of manslaughter, on the 19th ult. (see Medical Gazette for the present season, vol. i. p. 266), was tried at the Old Bailey on Wednesday last. The same evidence as before was adduced against her, while, to prove that she had not caused the death of the patient, several persons were brought forward who were alleged to have been cured by her. One of them was a man whose hand she had restored from some complaint—we know not what. He struck the witness-box with great energy, exclaiming, "The hand that strikes the blow *were* the one she cured." The argument was convincing to the enlightened jury, who, without retiring or suffering the judge to sum up, returned a verdict of—*not guilty!*

* Bell's Observations on Italy, page 88.

MEETING OF MEDICAL STUDENTS.

In our last leading article we anticipated a meeting, which has since taken place. It is impossible to deprecate such proceedings in too strong terms: they are certain to do mischief, and cannot possibly do good. We believe that the so-called public meeting originated with a school which does not contain a dozen pupils, and that the others who were present went for the purpose of opposing and putting it down: in fact, there was a strong disposition manifested to inflict summary punishment on the mischief-makers. We repeat the caution we gave last week—"Nothing can have a more injurious effect, in the eyes of the public, than variance and disunion; which, on such a subject, would excite no sentiments but those of ridicule and disgust."

HOTEL DIEU.

CLINICAL OBSERVATIONS ON HARE-LIP,

By M. Dupuytren.

Double Hare-Lip—Excision of the Bony Tubercle—Hæmorrhage—Death.

A child of three months old was lately brought to the Hôtel Dieu, presenting a double, and rather complicated specimen of hare-lip. On the right side the division occupied the whole depth of the lip, all the palatine vault, and the velum pendulum; on the left side the fissure was neither so profound nor so extensive. The middle portion had its base so near the nasal spine that it was thought possible to make it assist in the removal of the deformity. It was therefore separated from the bony tubercle, and this was extirpated with a pair of scissors: it included the germs of two incisor teeth. The rest of the operation was postponed till another day. There flowed at first a little blood, but this appeared in a short time to have ceased; however, the child continually performing the act of suction, gave rise to its recurrence, so that it was found necessary to apply the cautery. Some blood, which had been swallowed, was voided by stool, and on the day appointed for the completion of the operation, the child was too weak, so that it was again deferred. Nevertheless, the exhaustion continued to increase; the middle portion of the lip sloughed; and the child rapidly sunk. No autopsy was made.

M. Dupuytren observed, that notwithstanding the progress of science, and perhaps even in consequence of that progress, there are very few diseases whose history is so clearly made out as not to give rise to constantly renewed discussion on important circumstances connected with it. The course of his clinical investigations had led him to discuss two capital, and as yet undecided points in the history of hare-lip, viz. the period most fit for operating, and the treatment most applicable to a complication of the disease, as yet but ill understood.

It is well known how much the opinions which have been given on the first of these points differ from each other: some operate immediately after birth—others wait till the fourth or fifth year, to afford time for the intellect of the child to be developed; yet others trust little to the degree of reason possessed at this period, and postpone it still longer.

According to M. Dupuytren, the flesh is so soft at birth that it is easily torn by the needles, and the operation thus rendered uncertain; besides which, the mortality being greater at this age than any other, it would be imprudent to add a new source of danger to those which already exist. Such are the inconveniences; and it becomes a question whether they be counterbalanced by the advantages. Doubtless it would be desirable by the performance of the operation to give the infant an increased power of sucking, so that it might be able to take the breast; but this instinctive desire to be suckled, and the act of suction which it occasions, is one of the very circumstances most opposed to the success of the operation. If by any means this could be got over, then the earliest possible period would gain a powerful argument in its favour; but the tendency to suck is manifested from the moment of birth, and is unconquerable.

The one alluded to, however, is after all not the most objectionable that can be selected; and it is difficult to conceive what can have led so many to give the preference to four or five years of age as the time of operating. On the allegation that the child was then old enough to be conscious of the necessity, and to anticipate the advantage of the means adopted; so that it would thus consent to the proceeding, and submit with more fortitude to the pain? Experience might well have undeceived them. At this age, children have just intelligence enough to anticipate—to feel and to remember pain, but without their reason being of any avail in assisting them to bear it; they endeavour to escape from it as much as depends on them, and do every thing in their power

to embarrass the operation. At the very most is it possible occasionally to gain a short stillness and tranquillity in girls, to whom coquetry is already not unknown, and who are easily flattered; but as to boys, with them this motive goes for nothing, and they are completely intractable. Recently, said M. Dupuytren, I have verified this by experience.

At a later period, reason and courage are both more developed; but if the bone participates in the affection, their increased compactness leaves less room to hope for their re-union. Under every circumstance it is advantageous to operate early: thus the entire deformity is less, and that which depends upon the separation, or displacement of the bone, may be entirely overcome. For these several reasons, M. Dupuytren prefers operating at three months: life is then less precarious, and the chances of mortality more favourable than at birth: the infant feels the pain, indeed, but does not dwell upon it, and has no anticipations to distress it. Many surgeons already select this period, but more apparently by custom than calculation: at least, said M. Dupuytren, I know of no one who has recommended it on this ground.

M. Boufils, of Nancy, who has had extensive experience in such cases, operates immediately after birth. At this time he says the infant suffers little—scarcely cries during the operation, and becomes quiet when it is over. He states that the instinct of sucking, if not strengthened and confirmed by the infant being put to the breast, subsides, and that the inconvenience abo e alluded to is thus to a certain extent overcome. The infant is to be nourished by milk poured into its mouth. His plan is to lay the patient on a table, forming an inclined plane by means of pillows, and to have him confined by bandages: the edges of the division are then pared with the scissors, and the bleeding is restrained by compression applied with the fingers of an assistant to the maxillary artery; and, subsequently, simply rubbing the cut edge is sufficient to arrest the bleeding. It is desirable to prevent bleeding as much as possible, because the blood being swallowed is apt to cause vomiting, which seriously interferes with the success of the operation. The divided parts are then brought into apposition, and retained by means of two needles. No bandage is used, but an intelligent nurse is made to place the babe on her knees, and sit with the parts gently pressed and approximated between the fore-finger and thumb: when tired she is relieved by another, and thus the juxta position of the divided edges is maintained and adapted to the circumstances, being especially directed when the infant cries, laughs, or takes food. Three or four days suffice for the union to be accomplished. The needles are then removed, but the thread, which by this time has become as it were glued to the skin, is left undisturbed. Small adhesive plaisters are now applied. Should circumstances induce us to prefer the early operation, this is the manner in which it may be conducted with the best prospect of success.

But whether the operation be performed sooner or later, another important question is involved in the complications which sometimes present themselves. When there is a projecting tubercle in the middle, with two deep lateral fissures, an attempt is made either to remove the portion of bone which supports this, or else we endeavour to force it back into its proper place; and those writers who have vaunted of their success, have doubtless thought but little of the degree of deformity produced—at least they have passed it over in silence. When the labial tubercle projects forwards, said M. Dupuytren, it is necessary to give attention to the point at which it is inserted into the partition of the nose, for on this often depends both the degree of the projection and the proceeding to be adopted. When the insertion is near the point of the nose, if the tubercle be attached to the lateral portions of the lip by an operation, these have a tendency to pull it backwards, and the point of the nose follows the movement; the alæ of the nostrils are thus separated, and the entire nose remains flattened, having a very disagreeable appearance. I have more than once had to regret, said M. Dupuytren, having substituted one deformity for another in the children operated upon in this manner, and that, too, scarcely inferior to the natural disfigurement. What would it be, then, if the tubercle were inserted actually at the point of the nose?—a circumstance by no means very rare, and several times witnessed by M. Dupuytren. In a recent instance of this kind, where he was called upon to operate, he contrived the following method:—The fleshy tubercle was separated, with a bistoury, from its bony support, and this last cut out with sharp pincers; the fleshy part was then easily carried horizontally backwards and converted into a partition for the lower part of the nostrils, between them and the mouth. Then, whether the union of this part was allowed to take place first, or whether the hare-lip operation was completed at once, it was reduced to one of great simplicity, and performed with needles in the usual way.

M. Dupuytren tried this plan some time ago, on a child—unfortunately a very in

docile little patient, and whose struggles involved the operation in much difficulty. The bony tubercle having been removed, and the skin carried backwards to form the floor of the nostrils, it was maintained in its position by a bandage, and the farther steps delayed till union had occurred. On removing the dressings the adhesion appeared to be complete, but the movements of the infant caused some slight hæmorrhage. The assistant thought he could not do better, with a view to arrest this, than lay hold of the tubercle with his fingers; and this was sufficient to break down the connexion, which was still very weak. The hare-lip operation was performed, nevertheless; the needles were placed in their proper situations, though with extreme difficulty, owing to the incessant struggles of the child. Below, adhesion took place very satisfactorily; but above, there remained an opening as large as a pin's head. In a second case, M. Dupuytren has carried the plan successfully into effect.

It is only when the labial tubercle is inserted near the nasal osseous spine that it ought to be preserved as an intregral part of the lip. In this case, also, M. Dupuytren reserves a portion of the adjacent bony tubercle: an operation, however, which he admitted, as in the preceding instance, not to be free from danger. He stated, that the blood which is swallowed in these cases never became digested, and that, in general, it is returned by vomiting. In the present case it remained longer than usual, and as, under such circumstances, it is apt to become more or less decomposed, he advised the application of laxative clysters for its removal.

MILITARY HOSPITAL OF INSTRUCTION, ALGIERS.

CLINICAL OBSERVATIONS ON WOUNDS FROM FIRE-ARMS.

By M. Baudens,
Surgeon-in Chief, and Professor to the Hospital.

WOUNDS OF THE NECK.

We have had many cases in which balls had traversed the integuments and superficial muscles of the neck, without occasioning bad consequences: we have always been able to manage them by topical refrigerants, bleeding, low diet, and repose. But the following examples are worthy of detail:—

Lesion of the Primitive Carotid — Fatal Hæmorrhage.

A soldier received a shot before my eyes, which was followed by a tremendous and mortal hæmorrhage: it was from laceration of the primitive carotid. I secured both ends of the artery in a moment with ligatures; but in vain: the man sunk exhausted. Same day a soldier of the 30th regiment received a shot in the popliteal nerve and artery, which proved fatal from the immense hæmorrhage that ensued in a few moments. Probably transfusion might have been employed in these cases advantageously; and whenever I have an opportunity again I shall try it. But though I might have restored the latter individual by such an operation, I should have had to amputate his thigh after all, in consequence of the simultaneous lesion of the artery and nerve.

Ball lodged between the transverse Processes of the fourth and fifth Cervical Vertebræ—Lesion of the Brachial Plexus—Paralysis—Cure.

A soldier was struck with a ball, which traversed laterally the soft parts of the middle of the neck, and lodged between the transverse processes of the fourth and fifth cervical vertebræ of the right side, where I recognized its presence with my finger. The shot had probably torn the nervous branch of communication between the cervical plexus and the brachial, the latter being itself the seat of considerable injury, appreciable in the occurrence of a sudden paralysis of the whole thoracic extremity. I dilated the orifice of the wound to above two inches, and succeeded in extricating the ball, though not without great difficulty. I removed also a small splinter, the point of which might have occasioned the worst consequences, by pressing upon the plexus. The wound healed well; after which, by the diligent application of stimulating liniments and of moxas at the origin of the brachial plexus for several months, the arm, which was somewhat spent, resumed its nutrition, and recovered eventually the perfect exercise of all its functions.

As I knew by experience that the ball, left to itself, would probably, as it does in many cases, make its way out in the process of suppuration, I should not have been so anxious to extract it, if I had not dreaded the possible occurrence of tetanus which its pressure on the plexus might occasion. And although we sometimes find these foreign bodies remaining for an indefinite period in the human body, wrapt in cysts, and producing no ill consequences, yet it is more frequent to find them productive of suppuration, and even of caries, which can be relieved alone by extraction.

Perforation of the Œsophagus—Cure.

I found, at the ambulance, a soldier of

the 28th regiment, who had several hours previously been wounded with a bullet, which passed through the middle of his neck from left to right. By the exit of whatever he drank through the wound, it was easy to perceive that the œsophagus was injured. The man did not complain of much beside the intolerable thirst which he felt, and was not able to satisfy. I introduced a tube into the stomach with much care, and with the help of a syringe injected some emollient drinks; then, having suppressed the inflammatory symptoms by means of antiphlogistics, I ventured to give him some soft and nutritive food. The poor creature could only appease his thirst by sucking some morsels of orange. In a short time, by the employment of a methodical system of compression with caustics, the fistulous opening was closed, and the patient could himself introduce the tube without assistance. The œsophagus, in consequence of the cicatrix, presents a manifest contraction, which will oblige the patient to avoid all food that is not liquid or soft. But how are we to account for this extraordinary wound and its cure? How did the trachea, the front of the vertebral column, the arteries, and the nerve of the eighth pair, escape all appearance of injury? I can only suggest the unequal retractility of the different tissues, the attitude of the individual at the moment he was shot, perhaps also the change of form which might have been undergone by the projectile, flattened by some hard substance against which it previously struck, the deviations of the bullet, and the great elasticity of the trachea, as possibly capable of throwing some little light on a very difficult question.

ST. BARTHOLOMEW'S HOSPITAL.

Case of Retention of Urine and great Tumefaction of the external parts, produced by a Calculus, impacted in the Urethra of a Child.

John Jacques, a fine boy, aged 4 years, was brought to the hospital about nine o'clock on Friday morning, the 26th of October, and placed under the care of Mr. Earle: on his arrival the whole scrotum and skin of the penis were found to be very œdematous, and much increased in size: the woman who accompanied him, knew nothing further of the case than that the swelling had suddenly made its appearance early the same morning. Numerous scarifications were made with the point of a lancet, to relieve the excessive tension, after which, warm fomentations were continually applied. At two o'clock, P.M. the tension had rather increased than diminished, notwithstanding that a considerable discharge of blood and serum had been kept up by the warm applications. On examination, no stricture of any kind, or other exciting cause, could be discovered; the affection was therefore attributed to irritation, produced by some acrid secretion under the prepuce, which was exceedingly œdematous, and in a state of phymosis. A weak solution of sulphate of zinc was ordered to be thrown up under the prepuce by means of a small India-rubber bottle.

At seven, P.M. the boy having made no water since the morning, and the œdema having increased to a frightful extent, an attempt was made to pass into the bladder a very small elastic gum catheter, but without success: a slit about three-fourths of an inch in length was then made in the upper part of the prepuce, but as the glans penis did not then make its appearance, some slight doubt arose as to the nature of a tumor, which resembled somewhat in shape and even in colour the glans penis in a state of disease: a slight puncture was made into it, but as no thing but pure blood oozed from the wound, no light was by this means thrown on the nature of the enlargement. The penis was again carefully examined, the œdema having somewhat diminished by the bleeding, &c.: a slight irregularity was discovered by pressing firmly the penis between the finger and thumb, at about three-quarters of an inch from the pubis; and as this was the only irregularity felt, it was presumed to be the glans. The director was again inserted under the prepuce, and the incision continued to this point, when the tip of a small calculus was discovered at the orifice of the urethra, which was removed without much difficulty. In shape, the stone is a long square, about the third of an inch in length, a quarter in width, and two lines in thickness: one extremity forms a kind of wedge-shaped head, the very tip of which was the only part discoverable at the orifice of the urethra. A small elastic gum catheter was immediately introduced into the bladder, when about sixteen ounces of urine were drawn off: some further scarifications were then made in the prepuce and scrotum; a hip bath was ordered to be used immediately; and the parts to be enveloped in a bread and water poultice during the night.

27th.—A considerable quantity of water is stated by the sister to have dribbled away during the night; and the boy appears to be doing well.

29th.—Yesterday a small dose of castor oil was given. The water is made freely, but still in the bed. The belly this morning appears distended, but no external examination can give an exact idea of the state of the bladder, as the boy cries immediately on turning down the bed-clothes. The catheter has been introduced into the

bladder, which was found to be empty. The scrotum is still swollen and much inflamed.

Ordered a hip bath, and to continue the poultices.

30th.—The scrotum still inflamed; has not passed much water during the night; the catheter was again introduced, and a large quantity of highly-coloured urine drawn off.

Repeat the bath and poultices.

31st.—A considerable quantity of matter had formed around the root of the penis, which has been let out by a free incision: a large arterial branch was wounded, which required to be tied.

Nov. 2d.—Another incision was made to-day on the opposite side of the root of the penis, as there was still a small collection of matter. The boy is rather blanched and weak.

Ordered to have meat diet, and a little beer.

6th.—Since the 2d, no unfavourable symptoms have appeared; the boy now makes his water freely into a vessel, and none escapes through either of the wounds; in the urine there is a considerable deposit.

Fear was for some time entertained from the suppuration in the cellular tissue of the scrotum, that ulceration of the urethra, and consequent effusion of urine, had taken place, from the irritation caused by the passage of the stone, and the introduction of the instruments; but the mischief has been so limited, that all fear on this head is dissipated, and especially as no water has passed through either of the wounds.

This case shews of how much importance it is to investigate minutely every case as soon as it presents itself to our notice, and of what value may be the statement of the friends, should the patient from age, the disease itself, or any other cause, be incapable of answering rationally those questions which it is necessary to put to him. Had the mother fortunately accompanied this little patient to the hospital, and given the subjoined statement, which she made the following Sunday morning, no doubt could have been entertained of the propriety of at once having recourse to those means which were resorted to ten hours afterwards, and thus the patient would have been saved much unnecessary pain and suffering, and the risk of his life.

The mother stated that on Thursday morning, (the morning previous to the boy's being brought to the hospital,) immediately after going to stool, he ran in, crying, and saying that "he had run a nail in." As no wound was discovered, she thought nothing more of it, although he complained more or less of a pricking sensation during the rest of the day. The following morning, about six o'clock, on again going to stool, he again returned with the same exclamation: on examination, the parts were discovered to be slightly swollen. The swelling increased very rapidly, as at nine o'clock he was brought to the hospital in the state above described.

ROCHDALE DISPENSARY.

To the Editor of the Medical Gazette.

Sir,

If you consider that the following cases, with the observations attached to them, merit a place in your widely circulated and valuable journal, they are at your service.

Yours respectfully,

Robert Barker,

House Surgeon to the Rochdale Dispensary.

Nov. 21, 1832.

Cases of Phlegmasia Dolens in the Male.

Charles Brearley, ætat. 17, a carter, was admitted as a patient on the 17th of April. He stated that about a week before he was seized with a pain in his right groin, followed by shiverings, thirst, and other febrile symptoms, for which he took a purgative powder. At the period of his admission, the upper third of the right thigh was immensely swollen, tense, and elastic; extremely hot and painful, but of a natural colour. Violent re-action; the pulse strong and full; stomach rejecting every thing.

An attempt was made to ascertain the state of the absorbents and lymphatic glands in the groin, but from the rigid condition of the integuments and painful state of the limb, no accurate information could be gained.

He was twice bled, generally and locally, and freely purged, &c. A cold lotion was afterwards applied to the limb.

21st.—The swelling of the limb extending downwards towards the knee, and upwards round the hip. Fluctuation is indistinctly discernible in the upper third of the thigh; the integuments are very much distended, and elastic, and present a smooth shining appearance, without the slightest discolouration.

Perstet. in usu medicament. (ten grains of Dover's powder at night); Imponatur Catapl. Lin. part affectæ.

22d.—Has passed a good night, and experienced great relief from the poultice; is better in other respects, but his pulse is 110; fluctuation a little more distinct, and is not confined to one part of the limb, but is perceived all round. The leg and

foot considerably swollen. The flexor muscles of the leg, as also the adductors and flexors of the thigh, so contracted as to form right angles; the former with the thigh, and the latter with the body.

℞ Tinct. Digitalis, ʒj.; Mist. Camph. Aquæ Puræ, a.a. ℥iij.; Syr. Rhæados, ʒij. M. ft. mist. cujus coch. duo ampla. quartâ quâque horâ sumantur.

℞ Pul. Ipecac. comp. gr. x. ft. Pulv. hora somni. sumend.

Diet to be nourishing, with wine or porter.

23d.—Has rested tolerably during the night; vomits the mixture; thigh much as yesterday. Pulse still very quick. Appetite very good, and abundantly supplied with nourishing diet.

Contin. Catapl.

℞ Hydrarg. Submur. gr. x.; Opii in Pulv. gr. iij.; Antim. Pulv. gr. vj.; Acaciæ Mucil. q. s. ut ft. massa in pilulas viij. dividenda quarum sumat unam tertiâ quâque horâ.

29th.—The fluctuation more evident, and equally felt round the whole limb; pain upon pressure very acute.

A large abscess lancet was pushed into the centre of the anterior aspect of the thigh, about one-fourth from the upper part, and an opening two inches long was made, but nothing followed the withdrawal of the lancet. The integuments immediately retracted, making the incision appear circular instead of longitudinal; under this tissue the opening was entirely closed. In a few minutes a very thin pus began to ooze from the opening, and, during the next twenty-four hours, twenty ounces were evacuated: external pressure did not increase the discharge. The tension and pain were considerably diminished by the evacuation of matter, and, upon examining the limb, an irregular knotted character was distinguishable. Any attempt to extend the limb was attended with the most acute pain.

The treatment, for the following three weeks, consisted of anodyne fomentations and poultices to the thigh, and nourishing diet as before. During this period, two other openings were made similar to the first, with like results; only that the matter, when discharged, was of a bad odour.

He was ordered Quina, with Sulphuric Acid.

From this time the patient gradually improved, the extensive thickening about the hip daily lessening under the use of anodyne frictions; towards the middle of July he was able to sit up, and there is now every hope that the use of the limb, to a great extent, will be restored.

I have been induced to draw up this case from the rareness of its occurrence in the male, it being the same or very like the disease designated "phlegmasia dolens," and described as nearly peculiar to the puerperal female. The case of the late Lord Liverpool, published by Sir Henry Halford in a late number of the Medical Gazette, is the only undoubtful case in the male I have been able to find on record, save one mentioned in Dr. Mason Good's Study of Medicine, which happened to a Dr. Booty, and is described as having been very similar to phlegmasia dolens.

Mr. Bower, a highly respectable surgeon of this town, informs me that two cases similar to the above have occurred in his practice, which I shall give in his own words.

John Travis, æt. 58, farmer, of spare habit, and exposed to all vicissitudes of weather, was seized, on the 24th of May, 1828, with violent and deep-seated pain in the left groin, shooting down the thigh in the course of the femoral vessels as far as the ham, with a sense of coldness of the leg and foot. He had a severe rigor in the early part of the day, followed by heat generally diffused over the body except the leg of the affected side, which preserved its natural temperature, although the patient complained of a sense of coldness in it. On a careful examination of the limb, not the least swelling or induration could be perceived, but some tenderness on pressure along the upper and inner part of the thigh. He was bled from the arm, had leeches applied to the seat of the pain, was freely purged, and at bed-time took ten grains of Dover's powder.

25th.—Passed a restless night; pain increased; thigh and leg enormously swollen, tense, shining, perfectly elastic, and of a natural colour.

Temperature of the whole limb somewhat less than the rest of the body; complains of great debility, and the fever assumes a typhoid character.

Ordered leeches to be repeated; afterwards a large cataplasm to the groin, and frictions, with stimulating liniments, to the leg and foot. To take Dover's powder at bed-time.

26th.—Limb still swollen, but preserving the appearance of yesterday.

To continue frictions, with Dover's powder.

He continued much in the same state during the ensuing ten days, with slight delirium during the night.

June 6th.—Improved in every respect; limb somewhat diminished in size, and the skin slightly puckered; no pain; fever abated; appetite improving.

9th.—Limb has nearly recovered its usual size; patient feels stronger, and wishes to get up. He progressively im-

proved; and, on the 20th, resumed his occupation.

The other case occurred in a young man, 24 years of age, of leucophlegmatic temperament, and of dissipated habits. His case presented the characters of the preceding, except that a small abscess, formed in the middle and inner part of the thigh, was healed very slowly. The same treatment was pursued, but his recovery was more protracted. He afterwards died of phthisis. His body was not examined.

If the preceding are admitted to be cases of *phlegmasia dolens*, of which there can be little doubt, if phenomena are allowed to be the characteristics of disease in both sexes alike, they tend to disprove all the theories of the French writers, as also of the English, which are founded upon the existence of some derangement of the pelvic or other functions connected with generation in the female; whilst they strongly corroborate that of Dr. Hull, which does not imply the disturbance of any function that may not occur to the male as well as female; and it also adequately explains the phenomena of the disease.

"THE FACULTY OF MEDICINE" AND DR. ELLIOTSON.

We stated last week, in reference to the solitary point in our answer to Dr. Elliotson which it has been attempted to refute, that the opinion of his colleagues on the questions which have been the subject of his discussion with this journal, had not been expressed by them, *quasi* the "Faculty of Medicine." Nevertheless, the Doctor has addressed the Dean of his Faculty, hoping to obtain something more to the point than the meagre statement of the Secretary, which we mentioned in our last. The first answer having proved unsatisfactory, Dr. E. wrote a second time. His notes have not been published; but Dr. Thomson's, which we find have appeared elsewhere, we subjoin:—

"Tuesday Evening, Dec. 4, 1832.

"The Dean of the Faculty of Medicine, in the University of London, presents his compliments to Dr. Elliotson. No such determination as that stated in Dr. Elliotson's note, namely, 'that henceforth no opening address shall be permitted to be delivered until it has been laid before the Faculty, in order that the nature of its contents may be previously ascertained,' has been adopted *by the Faculty*. No proposition for such a resolution has been made *in the Faculty;* and, consequently, no resolution of the kind *stands on the minutes of the Faculty*."

"Dr. Thomson presents his compliments to Dr. Elliotson. He does not exactly comprehend Dr. Elliotson's question. He knows of nothing which occurred *in the Faculty of Medicine* which could authorize the statement made by the Medical Gazette.

"3, Hinde Street, Wednesday Morning."

Considering the quarter from which it proceeds, we are perfectly at a loss to account for the publication of these notes, or to discover the object it is intended to serve. They strongly corroborate the view we have already given, and given correctly, of the sentiments which prevail in Gower-Street. No one can read them attentively without perceiving how the matter really stands. Their form, and the words which we have placed in italics, afford a key to the whole.

WEEKLY ACCOUNT OF BURIALS,

From BILLS OF MORTALITY, *Dec.* 4, 1832.

LECTURES

ON THE

THEORY AND PRACTICE OF MEDICINE;

Delivered at the London University,

By Dr. Elliotson.

CUTANEOUS DISEASES.

DISEASES CHARACTERIZED BY BOILS.

The inflammatory and pustular diseases, gentlemen, of which I have to speak to-day, are two, and both are derived from brutes.

MALIGNANT PUSTULE.

The first is what is called by some writers the malignant pustule; by the French it is called *pustule maligne;* and I rather think it is this disease, but I am not sure of it, that is called by the Germans *milz-brand.*

Symptoms.—In this affection there is a carbuncle produced, very similar to the carbuncle of plague. I do not imagine that the disease is by any means well understood, but its existence is an undoubted fact. Occasionally it has happened, when animals have been skinned after dying of a particular disease in which there are pustules tending to gangrene, that the individuals who have skinned them have had carbuncular pustules of a dark colour take place on the surface, and from which they have perished. It is said occasionally to have arisen from persons having merely touched the blood of an animal which was killed while labouring under this disease; indeed, one instance is recorded, of a butcher being seized with a gangrenous inflammation in the face and speedily dying, after having put a knife, with which he had killed a bullock labouring under this disease, between his lips. Some suppose that disease of this description—a carbuncle tending of course to gangrene, and which bears a resemblance to the carbuncle of plague, is never produced but by the contact of the blood, or the secretions, or the body, or something which the body has touched, of brutes who have died of this disease; but Rayer considers that now and then it occurs spontaneously and sporadically; however, I should hardly think that he is correct. It is possible that the person may have touched something which had been in contact with the animal previous to having its skin off. The animal may have been sent to market, and contact is possible, just like the infection of scarlet fever and small-pox, without our being able to trace it.

Contagious, not Infectious.—I never saw an instance of this disease. I believe that in general it is not infectious, but merely contagious; it has been described by Morand, a French surgeon, in the History of the French Royal Academy for 1766. He there gives the cases of butchers and others, who have been affected with gangrenous erysipelas and carbuncles. He thinks it can arise even without an abrasion of the surface, if the blood of the animal be applied. Enaux and Chaussier described the pustule maligne in their work on the Treatment of Bites, published in 1755, and which is followed by a short account of malignant pustules. Two instances are mentioned in Hufeland's Journal for 1822, of diseases of this description, which proved fatal to two men. They had been wetted in the performance of venesection, with the blood of a cow labouring under the disease. In each case the chief inflammation found after death was peritoneal, and they had also bubo.

The pustules, or carbuncles, of this disease, have generally been observed among veterinary surgeons, shepherds, tanners, blacksmiths, butchers, and labourers—in fact, all those persons who were most likely to come in contact with brutes la-

bouring under the affection. It is said usually to display itself on those parts of the body which are uncovered, such as the face, neck, hands, shoulders, or arms—all those parts being uncovered in many descriptions of work.

There is an account of many people being seized with a disease in 1818, at Ostiano, in Italy. Thirty-five persons visited an ill-ventilated stable, which contained three cows and ten horses, one of which had laboured under an offensive discharge from the nostrils for twelve months. Eleven of them were seized with the disease, and all but one died. Violent pyrexia, pains, spasms, and boils, and at last a large carbuncle, characterized the first stage; gangrenous vesicles, and a typhoid fever, were the chief features of the second. Whether this was the same disease I do not know; but if it be, it would appear that where there is a want of ventilation, and many animals are crowded together, it may be infectious. You will find in Rayer an account of the disease. It is at present rather an object of curiosity than of practice, because I believe that no treatment does good; some persons, however, recommend the application of the actual cautery to the carbuncles when they appear. It is supposed by Rayer to bear a very great resemblance to the plague in human beings; but it is very likely, notwithstanding, to be a different disease.

GLANDERS.

The next disease is glanders. You are aware that this is a disease of horses, and that it is chiefly characterized, or very much so, by a profuse discharge from the nostrils, and that it occurs in two forms, the one acute, and the other chronic. When it occurs in the acute form, there is violent inflammation of the face of the animal, and gangrene very soon supervenes. In the chronic form there is little more than discharge from the nostrils, and the animal will continue to labour under this for a great length of time, though in general the disease, I believe, is not susceptible of cure. Some persons now say that they can cure it; but at any rate, up to the present time, it has been considered an incurable disease. It is a highly contagious, but, I believe, not an infectious disease. I believe no horse ever gets it unless the matter from another horse comes in contact either with an abraded portion of the surface of the body, or the mucous membrane of the nostrils, and some say not even then, unless the mucous membrane is abraded. That, however, I cannot speak about.

Farcy.—The disease sometimes appears in another form, and then, instead of being called glanders, it is denominated *farcy*. I do not know that I am quite right in dwelling on these matters, especially as I am not conversant with them; but as the disease may occur in the human subject, and as I have seen two cases myself, I think the glanders ought to be enrolled among the diseases of the skin. When the affection assumes the form called *farcy*, there are small tumors which farriers call *buds*, or small ulcers, about the legs; sometimes on the lips, face, neck, or other parts of the body. Sometimes these are so small, so few in number, and create so little inconvenience to the animal, that for a time they escape observation; at other times they are larger, more numerous, painful to the touch, and spread more rapidly; and in these instances a general swelling of the limb often takes place, particularly when the hind legs are attacked, and some degree of lameness ensues. These tumors or buds are at first hard, but soon become soft and burst, degenerating into foul ulcers of a peculiar appearance. The lines of communication between the buds or ulcers are generally very observable, and they consist of what the farriers call *corded veins*; but, in general, I believe they are enlarged lymphatic vessels, running from one ulcer to another.

I believe the term *glanders* derives its name from a gland under the jaw, which is supposed to be the seat of the disease. I do not know the origin of the term *farcy*. However, when glanders and farcy occur in horses, they are the same disease; for Mr. Colman says that he has inoculated a horse with the matter from farcy, and it has produced glanders, and *vice versa*.

Glanders in the Human Subject.—Now the disease has appeared in the human subject in both forms—farcy and glanders; and it has also appeared both in the chronic and acute character, but the chronic, I believe, has been noticed more frequently than the acute. In the chronic form there has been no tumor produced on the body; but in other cases tumors have arisen in succession, and have suppurated, and the patients have most of them died at last completely worn out. I believe in one or two cases patients have got better. You will find three cases mentioned in Mr. Travers's work on Constitutional Irritation; and though he does not seem to have been aware that they were glanders, yet it is proved that one of them was, because Mr. Colman took matter from a man and inoculated two asses, and they were seized with acute glanders; mortification and sloughing took place, and both of them perished. I will read one of the cases related by Mr. Travers:—"Nimrod Lambert, a healthy hackney coachman, æt. 32, in January, 1822, infected a chap on the in-

side of the right thumb, by inserting it into the nostril of a glandered horse, to pull off a scab. He remembered to have afterwards wiped the thumb with a wisp of hay. In the space of six hours he was seized with violent pain and swelling of the thumb; it inflamed rapidly, upon which he applied a poultice to it, and took some salts. On the third day he was suddenly taken ill whilst driving, with cold shivers and giddiness, and states that he entirely lost the use of his limbs for seven hours. At this time his arm pained him much all the way up, and on the following day it was streaked with red lines, and excessively swollen; the arm-pit was also much swollen and tender. In the evening of the fourth day he was carried to Guy's Hospital, where he lay during twenty-four weeks. Superficial collections of matter formed successively in the course of the absorbents. The corresponding portions of the integument sloughed, leaving extensive ulcers, which discharged an unhealthy and fœtid matter. The glands at either angle of the lower jaw, and those of the groin, became swollen, and he was much afflicted with pain between the eyes, and down the nose, and exulcerations of the membrana narium, attended with discharge. During the progress of the local disease, he had much constitutional illness. He totally lost his appetite, and was oppressed with nausea; complained of severe pains, with swimming in the head,"—and so on. An ass was inoculated by Mr. Sewell with the matter of this man's sores, and died glandered. This was proof positive of the nature of the disease. The termination of the case is not given; but the patient considered his constitution broken, and despaired of ever being again the man he once was.

Another case is mentioned in the same book, which happened to a veterinary student who slightly injured his hand in examining the head of an ass which had died of inoculated glanders. An ulcer ensued, and pain and inflammation of the superficial absorbents took place in a few days, and soon ceased. But the absorbents of the opposite arm became affected, and an abscess formed in it, and another at the lower part of the back. He became hectic; and at length suppuration occurred also in the lungs, in one of the kidneys, and successively in each knee-joint; after which he died.

Now this might have been a mere inflammation of the veins and absorbents; but Mr. Colman inoculated an ass over the maxillary gland, and at the margin of the nostrils, with the matter of the abscess of the arm, and likewise rubbed some upon the Schneiderian membrane. Glanders and farcy were the result, and the animal died on the 12th day of the experiment. Precisely the same was done with another ass, by the patient's brother, but no effect ensued, as the matter was not employed for several days, and had been left exposed to the air. He repeated, however, the experiment upon the same animal with fresh matter, and it perished of glanders and farcy upon the fourteenth day.

The possibility of the occurrence of the disease in the human subject is certain; but all these facts I was perfectly ignorant of when a man was brought to St. Thomas's Hospital with some inflammation on one of his cheeks, and gangrene of one side of his nose. He had been perfectly well, excepting some common ailment which he had experienced a day or two before. Small pustules were forming around his nose, and upon his cheeks; his face was very much swollen; one eye was nearly closed, and the other completely so, and he was a little delirious. There were soft tumors on different parts of the extremities, and, I think, on the trunk; they were red and hot, and I saw that there was evidently fluid. There was a profuse discharge, as in horses, from one nostril—I think only from one, but at any rate infinitely more from one than from the other, and that was the right nostril. The pustules on the face were phlyzacious, large well fed pustules, with a hard base. They existed on, and around the nose, but principally on the right side, where the gangrene, and also the discharge from the nostrils took place. The parts which were red were hot, dry, and shining; but the nose was dark-coloured, and on its right half, black, cold, and senseless. He died before twenty hours had passed. With respect to the treatment, it was inefficacious. He was bled—for his pulse seemed to justify bleeding—and the blood was buffed. The preceding history of the case is this:—Twelve days previously he was attacked by pain in the right hypochondrium, for which he took ten grains of pil. hydrargyri, and the next day felt quite well. Then, five days before his admission, a pimple appeared upon the right side of his nose, and while this increased and suppurated, the surrounding parts swelled and grew red, and the state of things became such as I have described. Five weeks before his admission he had gonorrhœa, for which he had taken mercury; but the affection for which he was brought to the hospital began only five days before his admission.

The nature of the disease was a perfect mystery; some called it one thing, and some another. I did not venture to give it a name, never having seen any thing of the kind before, nor read of such a case.

This occurrence took place in March, and the patient was under the care of Dr.

Roots; and it so happened, that on the following June I found a young man lying in one of my beds, who had been brought in an hour before, in precisely the same state. The nose and surrounding parts were exceedingly swollen, so that the left eye was closed completely and the right nearly. The tumefied parts were hot and of a bright red, with the exception of an inch of the left half of the nose, which was of a mulberry colour; precisely the same state of things that occurred in the other young man. A profusion of deep-yellow tenacious mucus, with a few streaks of blood, exuded from each nostril, but particularly from the left. Several hard phlyzacious pustules existed on the nose and adjacent parts—on the arms, thighs, and legs—and each was surrounded, in the latter situation, by a blush of red. A patch of the same colour was observed on the left elbow. His pulse did not justify bleeding; it was rather an undulation than a pulsation. I ordered him beef-tea, wine, and sulphate of quinine; but he was dead in a few hours. A drawing was made of each patient. [They were exhibited.] That of Dr. Roots's patient was executed by Mr. Solly, apprentice to Mr. Travers; and the other, which contains two representations (the one before, and the other after death), by Mr. Alcock. The nature of the disease not being suspected, no experiments were made, or we might have inoculated an ass, which is much cheaper than a horse. An ass will sometimes serve the purpose of a better animal; and as it is as easily affected as a horse, of course I should have preferred it for making the experiment.

This disease is not described by either Willan or Rayer; the knowledge of its occurrence in the human subject being quite new. Each of these patients was opened, but not very satisfactorily: the father of each boy was present at the time, and forbad us doing any thing which would disfigure the head, so that the Schneiderian membrane could not be examined throughout. We were not allowed to cut the arms and legs, to see if there were tubercles down on the periosteum. It is found in horses, that tubercles are formed deep in various parts of the body.

The disease would have remained a mystery to me, only that I was satisfied it was a specific eruptive fever depending on some specific cause: so far I went, and no farther; till I was one day shewn, some little time afterwards, a case in the MEDICAL GAZETTE, headed "Fatal Case of *Acute* Glanders in the Human Subject;" and I found that the case was precisely one of this description. It is described by Mr. Brown, a surgeon in the second regiment of dragoons. This man was seized, on the night of the 16th of April, with rigors, headache, and slight irritability of the stomach—all the symptoms which usher in an eruptive fever. However, he had great pains and stiffness of all the large joints, and these increased to an alarming degree. The left shoulder was rather swollen, though not inflamed; but the tumefaction became considerable, and of a livid hue. Similar swellings, but smaller, took place on the arms, legs, thighs, and sacrum; exactly as in these cases in the hospital. The tumors were insensible and hard; but in the cases in the hospital the tumors were soft. They were of a chocolate-colour, but acquired a deep vermilion, and soon became of a dark brown. One appeared upon the left temple, and the eye-lids became tumefied. The right nostril was gummed up with an inspissated discharge. The posterior fauces were much inflamed, and nearly of a purple hue. Several warty pustules, (which I have termed phlyzacious,) rose above the skin, in various situations around each of the tumefications, exactly as I have shewn you in the drawings. A cluster of tubercles was found in the cellular membrane—a perfect examination was possible here—a cluster of tubercles was found in the cellular membrane exterior to the pericranium of the left superciliary ridge, and in the right frontal sinus, exactly (according to the veterinary surgeon of the regiment) similar to those observed in the frontal and other sinuses of the horse after acute glanders. On dividing the various livid tumors down to the bone, the muscles appeared perfectly decomposed, and of a dark livid colour; and under each was a cluster of grey circular tubercles. The existence of these tubercles is so common in the glanders of horses, that one French writer takes this for a tubercular disease; and it is described under that name in a French Veterinary Dictionary. Now this gentleman adds—"It appeared that the patient had had the sole charge of a glandered horse for some time, which had been destroyed on the very evening of his attack; and that he had skinned him, and exerted himself a good deal in cutting up and burying the carcase. But these circumstances did not at first create the least suspicion, and his complaint was considered a very severe case of acute rheumatism, and treated as such."

I saw that the two cases in St. Thomas's Hospital were similar, and must have been glanders; and the difficulty was to ascertain whether the parties had had any communication with glandered horses. I had a great deal of trouble in endeavouring to ascertain the fact, and I could not prove it at last; but I found that each of these men, although they were in an

occupation that one would suppose would never lead them near horses, yet they had actually been in the neighbourhood of glandered horses. Further than that I could not prove; but it is a very singular circumstance that this was satisfacto ily proved. I found, with respect to my own patient, that he was a whitesmith, at Lambeth. I went there, and inquired whether he had any thing to do with horses; taking it for granted that, as a smith, he had. They told me that he had never been near horses – that he was a *white*-smith. However, I went to the workshop, and I found it situated in a mews. I then asked if there had been a glandered horse in the mews?—to which the father replied, "No;" but one of the men immediately said, "Why, don't you recollect there was a glandered horse in the stable for six weeks, just next the corner where Tom used to work?"—and then shewed me that the boards which separated the stable from the whitesmith's shop were so defective that the discharge from the animal's nostrils had come through, and occasioned so great a stench that the young man frequently said he should not be able to work unless the horse were taken away. I learned, that when this horse was being led to the knacker's, about a month before the commencement of this disease, it fell down exhausted at the door of the forge; that he went and patted it about the head as it lay, and took hold of the head while the rest endeavoured to make the animal rise. I also found that he had a number of pimples on his face, which were raw; and his father said that he recollected he had got a habit of continually wiping his nose with the back of his hand. So far I went; and though this is not proof, yet these are singular facts.

With respect to the man that came first to St. Thomas's, he was a tailor; and tailors not being famous for horsemanship, I almost despaired of being able to trace any connexion between him and a hors —had it been a goose, there would have been no trouble about the case. I had to go to Woolwich, and at last I found that the next door neighbour of the man to whom this lad was apprenticed had had a worn-out pony, and kept it in a filthy wretched shed opposite the two houses. I ascertained that the animal had the glanders, and was afterwards killed on this account; that this youth was in the habit of harnessing it, and getting into a little cart which it dragged, to have a ride. Nothing is more likely than that he had some of the matter from this horse brought in contact with him.

It so happened, that among the different persons to whom I mentioned these cases, was a general practitioner at Clapham. About a fortnight or a month afterwards, he told me of a case which he thought was of the same description. A young man (a pupil of the Veterinary College, and the son of a veterinary surgeon at Clapham) had been seized with a very severe acute affection of the knee-joint—apparently rheumatic—and with severe pains, just like the other cases. He proposed that I should see the patient, but the father put it off till the next day, and in the interim the son died. The symptoms before death were a copious sero-mucous discharge, occasionally a little bloody, from the eyes and nose; the Schneiderian membrane was excessively red and nearly excoriated, and the eyes closed. A pretty abundant eruption, very similar to small-pox, that is, phlyzacious pustules, but larger and hard, appeared in different parts, but particularly the neck. There was scarcely any sleep, but occasionally delirium, and at length convulsions; and the patient died. Unhealthy pus was found in the absorbents of the arm; the bursa of the knee contained a large quantity of pus, with flakes of coagulable lymph. He appeared to have had under his care, at Clapham, a horse affected with the farcy; I suppose he meant glanders. The ring-finger of the right hand, and the absorbents and axillary glands, became all at once inflamed and painful; but whether after any wound or abrasion could not be satisfactorily ascertained. The finger suppurated and was opened, and a few days afterwards he was seized with headache and pains in his limbs, which were considered rheumatic. Then, afterwards, there were pimples on the face and a profuse discharge from the Schneiderian membrane. No experiment was made in this case; but as experiments were were made by Mr. Colman and the brother of another veterinary pupil who perished of this disease, there can be no doubt, whether this was a case of glanders or not, that the disease does occur in the human subject.

You will find a paper of mine on this subject in the 16th volume of the Medico-Chirurgical Transactions. Unfortunately the Society would not publish the drawings, and therefore the cases are not so interesting as they would have been.

These are all the pustular diseases of the skin. It is true, some persons give that name to those produced by a blister or a tight shoe, and to those which are brought out by tartar emetic ointment; but there is no occasion for me to say any thing of them. This therefore

concludes all that I think it necessary to say on inflammatory diseases of the skin.

CONGESTIONS OF THE SKIN.

PURPURA.

I will now speak of those affections which consist in extreme congestion of the skin without any inflammation, and of this description are petechiæ, vibices, and ecchymoses. There is a particular disease in which spots appear on the skin; *petechiæ*, small spots—*vibices*, large spots—and *ecchymoses*, extravasations, which occur throughout the body, on the conjunctiva, even within the mouth and the body, so that blood will actually be poured forth on the various viscera. This disease is called at present in this country *purpura*. It was formerly called *petechiæ sine febre*, or *hæmorrhagia petechialis*. It bears a great affinity to scurvy, and some fancy it is the same diseases, but I cannot subscribe to that opinion.

This is a disease that frequently happens without any constitutional affection. I have seen persons going about with it, and yet quite well in other respects; and in other cases, persons have died *with* it. There is no such affection of the limbs, no sponginess of the gums, as is the case in scurvy. The disease, too, has often arisen without any evident cause, whereas scurvy, I believe, never takes place except from a deficiency of proper food.

Species.—If the disease occur merely on the surface of the body forming patches, it is called *P. simplex*. But frequently there is a bleeding from the mucous surfaces—bleeding from the mouth, from the stomach, and from the intestines. I once had a patient who died from bleeding within the head—died of apoplexy, and a clot of blood was found under the arachnoid membrane, which had oozed from the vessels of the pia mater. Sometimes the spots are large, and sometimes there is ecchymosis. There is no inflammation nor tenderness of the particular parts: it appears to be a mere congestion of blood. Rayer, I think, has very properly separated it from inflammatory diseases, and placed it in the order *congesta*. It is a very singular disease: I have no idea of its nature; I cannot comprehend its pathology. You will frequently see the white of the eye spotted, and the same circumstance occurs within the mouth. The discharges of blood from the mucous surfaces are sometimes very great. It is a disease, too, which occurs under the most opposite circumstances; occasionally with great debility, weakness of pulse, exhaustion; and sometimes with the most inflammatory state of the system, so that if you take away blood, it is buffed and cupped, and the patient is greatly relieved by it, and most probably gets well. In other cases, such treatment would be death. You frequently see similar patches on the stomach and liver. In severe cases, the patient is pale; he looks as if he were in a state of anæmia, and I dare say the blood is deficient. On the other hand, I have seen children with many hundreds of these spots upon them, and yet running about perfectly well. Sometimes there would appear to be a little inflammation connected with this congestion. It is sometimes attended with great tingling, and even little wheals, and it is then called *P. urticans*, to shew that it bears some affinity to urticaria. You will frequently see—though it is not this disease—such tenderness of the vessels in old people, that if they rest upon their arm, or knock their hand against a door, so as to produce the slightest bruise, ecchymosis will take place, and that has been called *P. senilis*. It conveys the idea that it is the same disease, but it is merely such a tenderness of the vessels that the slightest contusion produces ecchymosis. A person may have the disease for many years at the latter part of their life, and yet be perfectly well. You will often be consulted by patients on this occurrence, and it is right to know that it is ecchymosis, and should not be called purpura. It is merely a bruise, and may be produced on old persons with the greatest facility.

You know that petechiæ take place under many circumstances—frequently in typhus fever; frequently in small-pox between the pustules; sometimes in scarlet fever; it is very common to meet with them in dropsy, where there is great debility; they very often occur where there is extreme dyspnœa; sometimes in phthisis, where there is extreme difficulty of breathing. But there may be such debility of the vessels that the blood oozes forth; they allow it to escape, or there may be an impediment to the return of the blood, and the blood may be forced out. Frequently, however, no reason can be assigned for the disease: the person may be living as usual, when all at once the disease makes its appearance. The pathology is to me a perfect mystery.

Frequently Inflammatory.—It was at one time supposed that this disease always occurred with extreme debility; that the proper treatment for it was wine and brandy, good nourishment, opium and bark; but there is no doubt whatever that there is frequently an inflammatory state: although the skin is not in a state of inflammation, although these spots are not inflammatory, yet the system is in an inflammatory state, which is proved by the buffy and cupped state of the blood.

Treatment.—In regard to the mode of

treatment, I do not think there is any satisfactory or universal way of conducting it; but you must treat it according to the particular circumstances in each case. In mild cases moderate bleeding, or mere purging, answers very well, and I think I have satisfied myself that purging with colchicum answers better than other things. I have made observations upon this medicine in other cases: I have purged with colchicum and other things, and the difference has been very greatly in favour of colchicum. I am sure you will get rid of this disease sooner if you purge with colchicum than if you use any other means. Where there is strength of pulse, it is necessary to bleed, and bleed freely. I have seen patients lose two or three pints in a few days with great relief, and they have got well. A great number of cases are of this inflammatory nature, but by no means all. Others are of a different description, and wine, bark, and good nourishment, must be given. I recollect a case which occurred in a child where there was merely moderate debility, and the child was out every day. The disease was not intense, but these petechiæ existed, and under good nourishment and tonics it got well. But in extreme cases it is necessary to do more than this: to give wine and opium, and treat the patient as you would if he were sinking under typhus fever, or confluent small-pox, with typhoid symptoms. Where there is hæmorrhage, I have no doubt it would be best treated by oil of turpentine. I have no doubt, as it restrains hæmorrhage from the alimentary canal better than any other medicine, that it would restrain it under this particular affection. One of the most severe and successful cases that I ever saw treated was at St. Thomas's Hospital, by Dr. Roots. There were petechiæ, vibices, and ecchymosis, in every part of the body; great congestion of the liver, so that the right hypochondrium was distended, and blood was poured forth from different cavities. The patient was bled, and took oil of turpentine, and he got rapidly well. Certainly every one who saw him must have supposed that he was near death. I was much disappointed in a case of my own, which I treated in the same way: apoplectic symptoms came on; and on opening the patient, a clot of blood was found on the brain.

DISCOLOURATION OF THE SKIN.

Before I proceed to those affections which are of a structural nature, I may perhaps say a few words on those diseases which consist in a discolouration of the skin. Some of these are really not affections of the skin itself: for instance, in jaundice the skin is yellow; in chlorosis the skin is exceedingly pale; and likewise in anæmia: but on other occasions the skin is really itself discoloured; and among these are mentioned sun spots, and that blackness or blueness of the surface which is induced by the continued exhibition of the nitrate of silver.

ORGANIC AFFECTIONS OF THE SKIN.

The organic affections of the skin are for the most part of a tubercular nature: they are what is called lupus, or noli me tangere, cancer, and elephantiasis.

LUPUS.—Lupus is a disease more frequently treated by the surgeon than by the physician, and is an affection that is particularly seen upon the face, around the nose, and upon the upper lip. It is exceedingly intractable. There is a kind which occurs in scrofulous children which will frequently give way, perhaps spontaneously; and sometimes also to one application and sometimes to another. But there is another description which produces deep ulceration and extreme pain, and frequently appears to be somewhat allied to cancer. This is called *noli me tangere*, from its generally becoming worse if interfered with by medical men.

Symptoms.—Lupus is characterized by tubera, which are rather oval, and frequently flat, of a brownish red or livid colour, which increase and terminate in ulceration, and an ichorous discharge is then poured out, which concretes into crusts. It appears on the nose and cheeks, and sometimes upon the ears and chin, but it is calculated that eighty times out of a hundred it attacks the nose. The parts around become harder and harder, suppuration goes on to ulceration, till at last there is a great degree of destruction produced.

Treatment.—Some cases have been cured, it is said, by the application of caustics, and particularly by arsenic, but there is no rule for the treatment; and I believe in a great number of cases the disease resists all means.

CANCER.—With respect to cancer, I need say nothing, because I have already spoken of it when speaking of structural diseases at large. The particular treatment of cancer falls under the care of the surgeon.

ELEPHANTIASIS.—The next disease, of which I will speak briefly, is one of very rare occurrence in this country, and of which I have only seen two or three instances, viz. elephantiasis. It has been termed the elephantiasis of the Greeks, to distinguish it from another form which is local.

Symptoms.—In this disease the features become extremely altered, the lips very thick, the whole of the face and a great

part of the body beset with hard tubercles, so that a person could not be recognized by those who knew him previously to the appearance of the disease. It receives its name from the skin becoming as rough and as hard as the back of an elephant: the face is particularly rough.

It is considered by Rayer to be a chronic inflammation, and you may either call it so, or an organic disease of the skin, just which you choose.

It is characterized by numerous independent tubercles, of a livid colour, which are particularly developed on the face and ears, the upper and lower extremities, and likewise on the arch of the palate. The tubercles terminate either by resolution or small ulcerations, which seldom extend in depth or breadth. They are covered by adherent crusts, under which a cicatrix is formed. It may occur in any part of the body, but it occurs, like lupus, much more in the face than other parts. It has been said by a great many writers that the sexual desire becomes insatiable in this affection, but others deny this; and not only so, but go to the other extreme, and say it is extinguished. The only case which I have seen occurred in a person who came from Madeira; but it is also found at St. Domingo, and in the Isle of France.

Treatment.—It has been cured, I believe, by the exhibition of arsenic. Many cases have been improved by this medicine, and slight cases have been absolutely cured by it: for the most part, however, the treatment is very unsatisfactory.

Barbadoes Leg.—There is another disease which is called "elephantiasis," but it is local, and does not spread throughout the body, nor form tubercles; and as it commences in a thickening of the parts below the skin, it is mentioned by Rayer as a disease not of the skin itself, but as one of those diseases which extends from other parts to the skin.

This affection is what is called *Barbadoes leg*, and it is also called *the elephantiasis of the Arabs.* It is a local disease, occurring in the scrotum and at the lower part of the leg. The skin becomes diseased, but the cellular membrane beneath is the chief seat of the affection. It becomes excessively thickened and indurated; and at Barbadoes it affects sometimes only one leg.

Causes.—A friend of mine says it is produced by a kind of flea, which is not satisfied with being on the surface, but forms a bag beneath, in which it lays its eggs, from the continued irritation of which, he says, the disease is produced. How that may be, I do not know. The blacks suffer the affection in the West Indies, and they are very dexterous, by means of a needle, in dragging out the bag, so that no harm ensues; but if any portion be left, an egg usually remains, and the disease proves very troublesome.

ICTHYOSIS.—The next disease of which I will speak, and which is classed by Rayer in organic diseases of the skin, is one which you will every now and then see, and it is termed *icthyosis.* This is a disease not so rare but what every one may in the course of his life see perhaps a few cases.

It is classed by Willan with scaly diseases, but as the scaly diseases I have mentioned have been all classed with a number of others in the list of inflammatory affections, this could not come in with them. It is, moreover, although a scaly disease, necessarily separated in the arrangement of Rayer from pityriasis, lepra, and psoriasis, because all those scaly diseases are of an inflammatory nature.

Symptoms.—Now in this disease there is no inflammation whatever; the skin is neither red, tender, nor hot, but it is covered by a large number of scales. These scales have been supposed to resemble the scales of a fish, but they are not imbricated—they do not lie one over another, like the scales of a fish; indeed, in many parts, the skin looks more like the feet of cocks and hens than any thing else. This will give you the best idea of it. At a little distance from a person labouring under the disease, you would suppose that the skin was dirty, the scales which lie upon it being of a sort of bluish colour. Of course it exists in various degrees of intensity, and to various extent.

The constitution is not in the least degree disturbed; the health is not at all affected; there is nothing to be seen but this organic affection of the skin, the cuticle being formed with this diseased character.

Causes.—The cause of this affection is not known, but it occurs sometimes from original constitution. I had two brothers under my care last year for this complaint, (Med. Gaz. vol. vii. p. 636,) in each of whom, although they were living at a distance from each other, one at Greenwich, and one at Woolwich, it made its appearance without any obvious cause. It seemed to be constitutional, and occurred in the progress of their age. It has sometimes been known to be hereditary. The skin feels dry and rough, and there seems to be no perspiration; in general, the skin ceases to secrete a watery fluid. If the affection be more intense, it exhibits exactly the appearance that Alibert has represented as occurring on the knee, in plate xxxvii. and which he calls *icthyose nacrée.* You observe that none of the scales are imbricated, and they look more like the skin of a hen's foot than any thing else. This, at a distance, looks

like a very dirty leg. The affection will sometimes cover the whole body. It is said in books that it is not seen exactly over the furrow of the spine; but in the cases which I had in the hospital last year, or at least in one of them, that part was covered with scales exactly like the rest. The face in these boys was very little affected, but the back of the neck suffered pretty severely.

Treatment.—Now the disease is generally thought, I believe, to be incurable, at least that internal medicine has little power over it; pitch, however, is said to do good. Dr. Willan says, that he cured a lady by giving her pitch. The pitch was made into pills, and she took as many as she could swallow in a day—altogether one or two ounces. I gave each of these patients, certainly not so large a quantity as they could have taken, but each boy swallowed forty or fifty pills three times a day. One of them put them into his hand, and swallowed them as children do sugar-plums: he must have taken nearer two ounces of pitch every day than one. At the same time that I employed this treatment with one of the boys, I had him oiled with olive oil. He was sent to the warm bath, and when he came out he was regularly oiled, and in this way he got well. I of course was in perfect uncertainty as to whether it was the internal or external medicine that did him good—whether it was the pitch within, or the oil without; and being told that he had a brother in a similar state, I requested that he also might come and be cured. I gave him pitch only, and in a larger quantity than Dr. Willan had done, but he was no better for it. I then left it off, and had him oiled, not all over, but one extremity only, and that extremity recovered its natural texture, while the other parts remained as they were. It was singular, that if a part which had been oiled by chance touched one that had not, that is to say, if one leg touched the other, this last immediately improved, though not to the same degree. In this way the boy was perfectly cured. These two brothers went out of the hospital with their skins as smooth and as soft as any girl's, and for the time they were certainly cured, but whether the disease will return I do not know. The free application of oil in these cases answered perfectly. With regard to the latter boy, I made careful experiments with the pitch, the warm bath, and the oil; and such intervals elapsed between the various modes of treatment, that I was perfectly satisfied it was the oil which effected the cure.

In these boys the disease was quite of the intensity represented in Alibert's 37th plate. At one period I used linseed oil, but that did no good, it dried directly; the olive oil, however, retained its moisture for some time, and that answered completely.

Species.—The ordinary form of the disease is called by Willan *I. simplex*; but now and then it occurs in a much severer form, and then it is called *I. cornea.*

Now the latter of these species is a rare disease, and is of an hereditary nature. Several instances have occurred of it in the children of parents who had laboured under the disease, not perhaps appearing at their birth, but occurring, like *I. simplex*, at a certain time afterwards.

There is a family in Suffolk in whom it has appeared for several generations—three or four; and what is singular, always in the male line: no female has been known to have it. Every part of the body is covered with the disease excepting the face, the palms of the hands, the soles of the feet, and the glans penis. I saw one of these men, the grandson of the person who is described in the Philosophical Transactions. It was a famous family, called "the porcupine family" from the roughness of the skin. This man told me that the scales were shed every year. I saw him again the other day, and then they were in the act of falling off. The scales in this form of the affection all stand side by side, do not overlap each other, and when the limb is put in a certain position there is a pretty smooth surface, on which you may make a noise just like striking horn; but if the part be stretched, so as to separate it a little, you see the divisions between the scales. This plate [exhibiting one] contains an exact representation of the arm of the man when I saw him a little while ago. He described himself as the descendant of an American savage: I suppose he wished to make himself appear very wonderful. He every now and then comes to London to shew himself for what he can get. There is an instance of the hereditary form of this disease, published in the ninth volume of the Medico-Chirurgical Transactions, by a gentleman residing in Sussex, and which occurred in a female.

Treatment.—In regard to treatment, nothing, I conceive, can be done.

DISEASES OF THE APPENDAGES TO THE SKIN.

As to diseases of the appendages to the skin, such as of the nails, I must leave them to the surgeon; but there is one disease of the appendages of the skin which is very interesting; and although we do not see it in this country, we have specimens of its effects—I mean the hair.

TRICHOMA.—It sometimes appears that the bulbs of the hair become inflamed, a quantity of acrid stuff is poured out, the

hair becomes very much entangled, and grows, it is said, sometimes to a great length. This disease is properly called *trichoma*, and sometimes it is called *plica*; and having been common in Poland, it has received the appellation, *plica polonica*. From the inflammation that exists, the scalp becomes excessively tender. It is found that the bulbs of the hair are gummy, and filled with a great quantity of liquid, and the least touch of the hair induces very great pain. The fluid which is discharged is gelatinous, and sticks the hair together. Some have considered that the disease is contagious, but I believe that is not the case.

Causes.—The causes of this affection are not known. Some ascribe it to the cessation of the perspiration, but any disease may be ascribed to that. Why it occurs more particularly in Poland than other northern countries, is also inexplicable.

Treatment.—Then, again, as to the treatment;—you may recommend the warm bath, and all kinds of things. If antiphlogistic regimen be indicated by the strength of the system, and the heat of the part, we may suppose that it will do good: the treatment, however, is very unsatisfactory.

DISEASES OF THE SKIN AS A SECRETING ORGAN.

The diseases of the skin as a secreting organ have either been already mentioned, or will be mentioned hereafter. As to excessive perspiration, that I spoke of when speaking of intense secretions generally; and as to dryness of the skin, that is rather a symptom of other diseases. Dryness of the skin occurs particularly in ichthyosis, in diarrhœa, and in fevers. As to diseased secretions of the skin with regard to quality, it is very common, as we shall find in rheumatism, for the skin to secrete an exceedingly sour fluid, so that the perspiration smells something like sour whey. Occasionally parts of the body will sweat, as an idiopathic disease—either the hands or the feet. Many people are troubled with sweating hands, so that whatever they touch they moisten. This state, however, occurs particularly in the feet, and it is very liable to be of an exceedingly offensive character. Some persons are tormented with this only at certain periods of the year, but some have always very offensive feet, from the diseased nature of the secretions that take place there. Many servants, I believe, have lost their places on account of this misfortune: they have been discovered to have offensively smelling feet. I had a letter not long ago from a medical man, residing at a considerable distance from London, stating that he was in this condition. He was distracted—in a state of extreme melancholy, indeed, on account of the copious and offensive sweating which he experienced in the feet. He had consulted every one within his reach, but had derived no benefit. I advised a number of things that occurred to me as likely to prove beneficial, but I have had a second letter from him, telling me that they have done no good. I endeavoured to alter the secretion by purging, and by applying astringents to the feet; and I advised a number of other things, which I now forget, but which appeared to me rational: I was not, however, sure that they would do him good, and so far as I know they did not; for the second letter which I received betokened the same agony of mind as that under which the first was wrote.

This is all I think it necessary to say respecting diseases of the skin. I am afraid that I have detained you too long on the subject, and that you must think me tiresome; but I have skipped several, some of which are trifling: with others, again, we are so conversant that they do not require any observations, and some of them are not common in this country. For sound and practical information on the subject of cutaneous diseases, I cannot do better than refer you to the work of Rayer.

ON SOME EFFECTS OF INFLAMMATION OF THE MEMBRANOUS LINING OF THE LARYNX.

By John Wood,
Late House-Surgeon to St. Bartholomew's Hospital.

Inflammation, with swelling and thickening of the mucous membrane of the larynx, and of the subjacent cellular tissue, is not very uncommon; and it strongly claims our attention, from the suddenness with which its alarming symptoms often appear, and the rapidity with which a fatal result is frequently produced. This disease occurs chiefly in adults. In many cases it comes on almost insensibly, and proceeds slowly. It is not usually complicated with inflammation of the tracheal or bronchial lining, or with inflammatory fever. In its acute form it is generally attended with complete dysphagia, and in milder cases with impaired deglutition in a less degree. By these peculiarities it may

be distinguished from croup; and, when examined pathologically, its effects are found to differ from those of croup, inasmuch as the change of structure consists of interstitial deposition, and not of effusion, in the form of an adventitious membrane, upon the surface of the inflamed mucous coat.

Little doubt can be entertained that the writers referred to by Dr. Goelis as authorities that croup may attack persons of the age of forty and sixty, were mistaken in the nature of the affection which they considered to be croup. This talented physician, in deference to the opinions of certain authors, and not in consequence of having himself seen any case of croup at so advanced a period of life, states that no age is exempt from this disease ("nilli vitæ periodo hic morbus pareit.") Dr. Goelis adds, however, "præprimis tamen ætas infantilis a primo ad septimum ætatis annum ad eum est proclivis." He mentions that he treated a child at the breast, five months old, and refers to other instances of croup in sucklings. Dugès states that he has seen this disease in an infant eight days old.

"In no part of Britain, I imagine," says Dr. Cheyne, "is croup more prevalent than in Leith and its immediate neighbourhood; yet, in the course of nearly fifty years of extensive practice, in which he has attended many hundred cases of this disease, my father has not seen one instance of croup occurring after puberty, while he has attended many cases between the tenth and fourteenth year, both in delicate and robust children." Mr. Double, who never had occasion himself to observe croup in an adult, admits, after a careful examination of recorded facts, that it may sometimes happen after puberty, but that the occurrence is much rarer than has been supposed. Dr. Mills records a case of croup which proved fatal, in a Miss ——, aged twenty-six. "The lining membrane of the trach a and bronchi was found inflamed, and covered with coagulable lymph." On dissecting the body of a girl, aged twenty, who died suffocated after a few days' suffering, Mr. Latour found a membranous coating (couenne membraneuse) extending from the larynx to the division of the bronchia. Such unequivocal examples of the occurrence of croup at so late a period of life are, I believe, extremely rare.

The specimens of croup which I have seen in collections of morbid anatomy induce me to mistrust the statements of Dr. Craigie, that "it rarely affects the laryngeal membrane;" and that "the inflammation is seated in the tracheo-bronchial membrane solely." Bichat and other French pathologists have come to a very different conclusion respecting the seat of croup. Dr. Desruelles contends that it is essentially a disease of the larynx. Messrs. Roche and Sanson maintain that croup affects, almost always, the larynx and trachea. Dr. Bland, who, like myself, adopts the latter opinion, has accordingly denominated this affection *laryngo-trachéite*, a name which Dr. Desruelles has, I think, decried unreasonably.

The distinction of croup from other forms of inflammation of the larynx, and an accurate knowledge of the seat of obstruction in each instance, are essential to successful treatment of the different affections. General bleeding, so highly beneficial in croup, seems often to have aggravated the sufferings, and hastened the death, of those affected with œdema of the glottis. Had the pathology of croup been better understood, laryngotomy would never have been declared to be the most efficacious means of relief.

In parts where cellular tissue abounds, without any admixture of adipose substance, swelling is produced by different degrees of inflammation. The scrotum, for instance, may be thickened and enlarged by slow inflammation; or it may become tense and swelled by serous effusion, from active inflammatory affection. The like changes are observed in the prepuce and conjunctiva. They seem to exist also in the analogous submucous membrane of the glottis, according as it is acutely or slowly inflamed. "In many instances," says Dr. Craigie, "the margins of the glottis are occupied by an œdematous or puffy swelling, similar to that which occasionally affects the eye-lids, prepuce, and female *labia*,—from sero-albuminous infiltration of the submucous filamentous tissue, and the effect of which is to diminish, or in some instances to obliterate, the aperture which regulates the admission of air into the trachea."

To prevent obstruction in the mucous passages from accumulation of fat, the submucous membrane is reticular. This tissue is in small quantity and com-

pact where it unites a mucous membrane to cartilage or bone,—more abundant and loose between such a membrane and other soft parts. In the larynx, where it abounds most at the root of the epiglottis and near the vocal ligaments, it was stated by Bichat to be susceptible of serous infiltration, which might rapidly cause suffocation. In every such instance seen by Andral, a well-characterized chronic inflammation had existed, and the œdema was a mere secondary phenomenon. The previous disorder of the membrane may here, perhaps, have been merely increased by the supervention of a fresh exciting cause of inflammation, such as exposure to cold, improper diet, or any such source of aggravation. In other instances the chronic forms of the disease may supervene to the acute. Œdema of the glottis seldom occurs as a primary acute inflammatory affection. It is generally preceded, sometimes followed, by a mild form of inflammation.

The swollen membrane may be indurated, or softened, or have its usual consistence. Dr. Cheyne has found it "like a thin layer of flexible cartilage." Softening of the aerial mucous texture is much rarer than of the intestinal, but frequently occurs in the larynges of phthisical subjects.

It is often impossible to determine, during life, whether acute inflammation has caused serous effusion into the submucous tissue, or whether this part is swollen and thickened by gradual interstitial deposition. In his valuable "Observations on the Surgical Pathology of the Larynx and Trachea," Mr. Porter states, that the symptoms of chronic cynanche laryngea resemble in every respect those of laryngitis œdematosa; that the former inflammation commences so insidiously, and proceeds so slowly, as often to produce an incurable disease before the patient's attention is roused to the perilous nature of his condition; and that the latter is also occasionally very insidious in its approach. Two young men who had retired to bed at night without complaining, were found dead from this affection the next morning.

A modification of inflammatory action may produce a combination of both affections, and thus constitute an intermediate distinction (LARYNGITIS CHRONICA ŒDEMATOSA)—a variety described by Mr. Lawrence in the sixth volume of the Society's Transactions.

Inflammation of the membrane of the larynx may end in suppuration: this occasionally happens in the genuine unmixed form of the complaint. It is more frequently seen where laryngitis is complicated with erysipelas or some other disease.

It appears to me, that the term SPASM is often used unwarrantably to explain the deaths of persons who have shewn symptoms of diseased larynx, and that the common notion of spasmodic asphyxia is dangerous, as it leads to the use of opiates and antispasmodics in disorders essentially inflammatory, and only to be treated with success by those who early discover and appreciate their nature and tendency. Dissection, certainly, seldom discloses in the larynx a complete obstacle to the transmission of air: this is not necessary to produce death. If the passage be gradually narrowed, so as to prevent at each inspiration the ingress of a proper quantity of air, the properties of the blood are consequently altered. The circulation of the fluid in an unhealthy state, produces a general debilitating effect: this is augmented by the fatigue resulting from the increased exertions which breathing requires. The imperfect expansion of the lungs causes in them a state of vascular congestion and consecutive serous effusion, which impedes the return of blood from the head, and gives rise to turgescence of the vessels of the brain with effusion into the cerebral cavities. "Although," says Dr. Cheyne, in his remarks on Croup, "apparently the first of the vital functions which is arrested be respiration, yet this seems to arise from a want of muscular strength in consequence of failure of the sensorial power, the invariable result of defective supply of pure arterial blood in the brain." These patients, I believe, die more frequently from cerebral disorder and gradual exhaustion than from sudden or spasmodic suffocation.

Moreover, the effects of disease upon living structures are often materially modified, and occasionally obliterated, by death. As, on the one hand, necroscopic researches frequently reveal lesions which the symptoms had not caused to be suspected; so, on the other hand, these same symptoms do not permit a doubt that an organ is sometimes seriously diseased, although it may not appear so on dissection. Inflammatory

swellings, which in the state of life are red and prominent, disappear almost entirely after death. In watching a child, dying of erysipelas of the head and face, I was struck by the rapid disappearance of the swelling and redness. This case impressed on me the justness of the remark, that it is not right to infer that inflammation has not existed in a part, because it is found of a pale white colour on examination of the body. Andral, who states that the morbid conditions of the aerial mucous membrane are identical in its whole extent, has found it perfectly white in individuals who exhibited all the symptoms of inveterate bronchitis. The failure, therefore, to discover after death a change of structure, explanatory of the previous symptoms, is not a satisfactory criterion that no such change has existed. I do not, however, remember any instance, in examining the bodies of persons who have died, apparently in consequence of laryngeal, bronchial, or pulmonary disease, in which organic lesion was not found. Respecting laryngitis, Dr. Armstrong observes, that "respiration always grew more and more difficult, till at last death seemed literally to occur from suffocation, most probably occasioned by tumefaction within the larynx and about the epiglottis; as dissection shewed that considerable inflammation had invariably existed there, without any other appearances sufficient to account for the fatal issue."

The frequent absence of pain in chronic laryngitis is considered by Andral to be the more remarkable, as the healthy larynx is exquisitely sensible. Inflammation of the iris may close the pupil without spasm, or the sufferer be conscious of the loss of vision The changes which narrow the urethra, do not usually excite any serious symptoms in their early stage: the patient is often first alarmed by the diminution of the stream of urine. With respect to what has been denominated spasmodic stricture of the urethra, it is remarked by Mr. Lawrence, that in this case there is probably no real stricture in any part of the canal, but only an obstacle produced in some situation or other by the inflammatory tension, a partial enlargement in consequence of inflammation of some portion of the lining membrane.

The phenomena of asthma have been attributed to sudden involuntary contraction of some part of the air passages; and that kind of difficulty of breathing which is considered to be periodical, (although the recurrence of the paroxysms is very irregular,) has been designated spasmodic or convulsive asthma.

Whether we examine the phenomena presented during the paroxysms of asthma, or in the intervals between them, we shall in neither case find the least necessity for inferring that this disease is of a spasmodic nature. On the other hand, various circumstances concur to show, that this peculiar variety of dyspnœa results from vascular congestion of the lungs, and particularly of their mucous membrane. The increased determination of blood to the lungs may be accompanied with, and is, I believe, in many cases, a consequence of, some permanent alteration in the structure of the heart or large thoracic blood-vessels. This view of the pathology of asthma, and a due regard to the influence produced on the economy by that fear and agitation which are inseparable from great oppression of breathing, will enable us to account for the leading features of the disorder, both in its active and passive stage: during the former, for instance, the pallid surface of the body; the anxious and haggard countenance; the coldness of the extremities; the small, frequent, and occasionally irregular pulse; the copious flow of limpid urine, which does not begin until after the invasion of the paroxysm, and which, therefore, ought not to be said to occur "as in hysterical diseases;" the relaxation of the bowels, which have been described as acting with somewhat of the impatient hurry and imperfection of spasm; the excessive difficulty of breathing; the patient's eagerness to inhale cold air; the deficiency of respiratory sound, ascertained by auscultation; the gradual decrease of the severity of the attack; and the augmented secretion from the bronchial membrane, which marks its revolution. What better proof can be furnished of the unloading of gorged vessels, than the relief the asthmatic experiences by a spitting of blood, or by a copious mucous expectoration? In the intervals between the paroxysms, patients are apt to contrast present ease with former distress, and represent that they are quite well. "But in almost every case," says Dr. Forbes, "there will be found, on examination, some permanent local disease of the organs of respiration, or of some other organ." Dr. Forbes likewise admits (and this admission is the more

remarkable as emanating from a believer in the opinion, that the asthmatic fit consists in a spasm of the muscular fibres of the bronchi,) that "diseases of the bronchi, which produce a similar contraction of the air-passages by mere swelling of the membrane, namely, bronchitis, and an affection producing nearly the same physical condition of the parts from a sudden congestion of the blood-vessels, give rise to a state of respiration very like that which obtains in the asthmatic paroxysm." If we further consider that this class of patients cannot endure the slightest unusual bodily exertion or mental emotion; that errors of diet, exposure to cold, in short any of those causes which disturb the balance of the circulation, especially such as produce irregular internal distribution of the circulating fluids, will commonly bring on a relapse; that asthma (like diseases of the arterial system, and unlike those of a spasmodic nature,) is more frequent in men than in women; that its obstinacy is proverbial; and finally, that, while narcotics and antispasmodics more frequently do harm than good, those remedies which determine blood to the surface of the body, diaphoretics, (particularly the ipecacuan,) the vapour bath, warm pediluvia, and warm diluents, are the most efficacious means of averting the attack;—we cannot but see reason to conclude, that this is neither a "*pure*," nor a "*sympathetic*," nor a "*symptomatic nervous affection*," but that it is essentially a disorder of the pulmonary vascular system.

Dr. Rostan, physician to the large hospital at Paris for infirm and aged women, has had peculiar opportunities of investigating this disorder, and has taken considerable pains to show that it proceeds from a surcharge of blood in the lungs. In all the dissections of asthmatic subjects made at the above institution during several years, changes of structure were observed in the large thoracic vessels, heart, or lungs.

When a permanent lesion exists, it is difficult to explain how the symptoms should be, as they sometimes are, only occasional, the intervals of the attacks being quite free from suffering. How, for instance, a person with an aneurism pressing on the windpipe, shall experience only now and then a paroxysm of difficult breathing; or another with a tumor encroaching on the brain, shall present merely occasional indications of cerebral derangement. If, as far as the larynx is concerned, this phenomenon be explicable by spasm, how are we to account for it when the brain is affected, unless by irregularity of the circulation?

The rapidity with which blood may flow to, or leave, a part of the body, and the rapid influence of the mind upon the circulating system, are both displayed in the act of blushing, and in the erection of the penis. In the latter case we can further observe, how suddenly the magnitude of an organ may be altered by a change in the action of the blood-vessels. The momentary dizziness and obscurity of vision, produced by placing the head in a position in which the return of blood is obstructed, show how quickly important functions may be disturbed from an unusual fulness of certain vessels, and how soon restored, as the repletion subsides, without the occurrence of any change of structure.

In whatever textures inflammation occurs, we notice periods of exacerbation and remission. May not, then, the occasional aggravation of the symptoms in laryngitis be as fairly ascribed to a temporary increase of the inflammation as to an extraordinary action of the muscles of the larynx? Are the distressing paroxysms in peritonitis ever attributed to spasm of the abdominal muscles? In tetanus, or in hydrophobia, where violent spasms in the throat are remarkable, do they every produce asphyxia? To conclude these desultory remarks on spasm, I have only to say, with the late Dr. Albers, of Bremen, "Neque adhuc vidi tracheitidem spasmodicam."

The early symptoms of certain forms of laryngitis are liable to be mistaken for a slight cold. This error caused the death of a patient who was entrusted to my care. Active measures were adopted as soon as breathing became oppressed, but were insufficient to counteract the mischief, occasioned by insidious inflammation.

A remarkable connexion is observed in the exanthemata, between the cutaneous disease and inflammation of certain parts of the mucous system. The throat, in particular, is apt to suffer in eruptive fevers. It is therefore in no wise extraordinary, that in some cases of erysipelas, the lining membrane of this part should be inflamed; and that, if this peculiar kind of spreading inflammation be allowed to proceed unchecked, it should affect the larynx and produce

suffocation. Rosen observed, in Sweden, the coincidence rather than the complication of croup *(laryngitis?)* with eruptive diseases. Rush frequently noticed the coincidence of croup with acute exanthematic eruptions. Dr. Albers states, that scarlet fever is very frequently accompanied with inflammation of the larynx; and that in small-pox and measles this organ is also apt to suffer. Yet, in the course of several epidemic scarlet fevers which Dr. Bretonneau had an opportunity of observing during twenty years, and some of which were so serious that a great number of patients died, it never once happened to him to see death caused by closure of the glottis from propagation of the inflammation to the larynx. Among the cases of œdematous angina related by Dr. Bouillaud, is that of a sempstress, who, in consequence of over-eating, became affected with erysipelas of the face, which extended to the neck and scalp. On the fifth day the erysipelatous inflammation was much increased; the throat was painful, deglutition difficult, and respiration accelerated. She died in a state of asphyxia on the seventh day from the commencement of her illness. Venesection was not employed, nor were leeches applied until two hours before death. On examination, the cellular tissue of the neck and of the larynx was found to be the seat of abundant serous infiltration.

Latour twice saw inflammation of the larynx in connexion with erysipelas; he found blisters very beneficial in these cases. Forestus mentions, that he attended upon a baker, who was nearly suffocated by cynanche of the throat occurring at the same time with erysipelas of the face: but whether the larynx was the seat of inflammation in this instance is uncertain, as the treatment was judicious, and the patient recovered. Dr. Stevenson has given an abstract of some cases of erysipelas affecting the face and head, and accompanied with inflammation of the fauces. In many of these instanses the disease terminated without extending further than over the soft palate, uvula, and back of the pharynx; but "in a few it spread to the larynx, producing a state of respiration very like that of idiopathic croup."

Of seventeen cases of œdematous laryngeal angina, observed by Bayle during six years, only one ended in recovery. This intelligent physician warned the profession not to be deceived by the apparent mildness of the disease, and recommended a prompt recourse to laryngotomy; although he appears to have possessed, at the time his memoir was published, no personal experience of the efficacy of this proceeding.

Dr. Baillie, after relating three fatal cases of inflammation of the larynx in adults, states, that the disease had a strong resemblance to croup, but is still to be considered as different from it; and that both general and topical bleeding when employed early and strenuously were of no use.

Dr. Armstrong witnessed a far greater mortality in laryngitis than in any other inflammatory disease. One of his patients died in eight hours, and another in seven, from the commencement of the symptoms. In another case, the loss of 160 ounces of blood, within six hours, gave temporary respite to the difficulty of breathing; yet, so far from arresting the inflammation, death took place within twenty-four hours, in despite of antimonials employed towards the close.

"Since my appointment to the Fever Hospital, I have seen," says Dr. Tweedie, "four individuals die from cynanche laryngea; *two of these were convalescents from scarlet fever*; and from what I observed in these cases, I am satisfied that when the larynx is attacked with acute inflammation, which generally terminates rapidly in œdematous swelling of the glottis, and the subsequent death of the patient by strangulation, the only chance of saving the unfortunate sufferer is by having immediate recourse to the operation of laryngotomy. This is more especially imperative when the disease occurs in connexion with fever, because, although the cases I have seen in the hospital, came on during the period of convalescence, yet the powers of the patient were not sufficiently recruited to admit of the active treatment a disease so truly alarming instantly demands."

Since bloodletting and other antiphlogistic and internal means, even when employed under auspicious circumstances, have generally failed to relieve that inflammatory affection of the laryngeal membrane which is attended with interstitial effusion; and since the few instances in which tracheotomy has been tried have been marked by signal success, it is to be hoped that the experience obtained by the loss of numerous patients,

will rescue from premature death many future sufferers from this insidious and destructive disease*.

CASES OF

OBSTINATE CONSTIPATION

SUCCESSFULLY TREATED.

To the Editor of the Medical Gazette.

SIR,

CONCEIVING that the following cases of obstinate constipation involved an interesting pathological principle, and a practical fact of some value, I send you them for insertion in your excellent periodical.

CASE I.—S. B. a female, aged 35, of the highly nervous temperament, who had suffered severely from spinal irritation, stated that her bowels had been confined for five days; that she had taken aloetic pills, senna and salts, and castor oil, without effect; and that she experienced a sense of fulness in the abdomen, with pain and tenderness, increased by pressure at the sigmoid flexure of the colon. Finding that active purgatives of every kind, whether saline or drastic, not only failed to operate, but aggravated the pain and tenderness; that enemata, even to the amount of two quarts, returned without effect; and that opiates and antispasmodics only occasioned confusion of head, it was determined to desist from purgatives; to counteract inflammatory tendency by small general bloodlettings, and by leeches, poultices, and epithegms of flannel wrung out of hot water, to the abdomen. Drachm doses of castor oil in mucilage, to promote a constant, but gentle peristaltic action of the intestines, were administered, every four hours; a slop diet was enjoined, a tea-cupful only at a time; and perfect rest in bed. On the *sixteenth day*, an evacuation was procured, preceded by the sensation of something having given way in the bowels; after which they resumed their regular action, and the patient recovered without any untoward symptom. She has for nearly five years enjoyed freedom from a similar attack.

CASE II.—E. P. a female, aged 23, subject to pain and tenderness along the spinal column, had suffered inconvenience from an irregular state of bowels. Evacuations were rarely procured without aperients, before obstinate constipation took place. She complained of pain and tenderness at the splenic flexure of the colon. The same expectant mode of treatment, guarding against inflammation, was pursued; and *on the tenth day*, a large, hard, dark-coloured stool was passed, after which convalescence proceeded without any untoward symptom; and the bowels, for a year and a half, have acted with greater regularity than formerly.

CASE III.—C. L. a female, aged 23, has suffered from spinal irritation, from obscure enlargement of the abdomen, and difficulty of bowels: at length, total obstruction ensued. Purgatives of every kind not only failed to operate, but occasioned pain in the abdomen, chiefly in the region of the sigmoid flexure of the colon. A moderate bleeding was practised, leeches were applied to the seat of irritation in the spine, and leeches and fomentations to the seat of pain in the abdomen. Under a similar plan of treatment to the preceding, at the expiration of *twenty-one days*, a copious evacuation of several pounds weight took place from the bowels.

The *pathological* principle which these cases illustrate is this:—that when spinal irritation exists, (indicated by firm pressure, percussion, or by the application of a sponge squeezed out of boiling water, occasioning pain in some part of the spinal column,) spasmodic contraction of the muscular fibres of the intestines, and consequent constipation may ensue; that the removal of this irritation, by means of leeches and blisters to the spine, is not alone sufficient to produce relaxation of the spasm, but that the dilatation of the contraction requires the slow and graduated pressure of the contents of the bowels, on the same principle as the bougie for the relief of stricture.

The *practical* fact is this:—that constipation of the bowels, unattended by any pathognomonic symptoms, is by no means dangerous; that the danger to be apprehended and guarded against is

* This is the valuable paper to which Sir Charles Bell alluded, in his lecture on Laryngotomy, in our last No. but one. By omitting only a few cases, and the references, we have been able to give the first part unimpaired, though it occupies more than 31 pages of the Medical and Chirurgical Transactions, from which it is taken.—E.G.

from inflammation, or from an attack of ileus; that the danger is augmented by the administration of active aperients, as evidenced by the increase of pain and tenderness, requiring vascular depletion, which purgatives occasioned, partly by stimulating the mucous surface of the intestine, and partly by forcing the contents too violently against the stricture.

But, by subduing the inflammatory tendency as it arose; by promoting the regular, but moderate peristaltic action of the bowel; by a slop diet, and that only in small quantity; by rest, and the uniform temperature of the bed, at length the stricture yielded, admitting of a free passage; whereas, under the heroic plan of treatment, increasing the strength and frequency of the purgative doses for the purpose of overcoming the resistance, *vi et armis*, a fatal termination of these cases might have been the result.—I am, sir,

Your obedient servant,
J. PIDDUCK, M.D.

VARIOLA AND VARICELLA DIFFERENT DISEASES; &c.

To the Editor of the Medical Gazette.

SIR,

IN Dr. Elliotson's Lectures on the Cow-pock, p. 307, of your last No. he is stated to have said that one of the surgeons to St. Bartholomew's Hospital "used to give gratuitous lectures against the cow-pock, in which he advised all the students not to resort to such a practice." Several other unseemly things are reported of this surgeon; but it is a mistake to suppose that he belonged to St. Bartholomew's. The surgeons of St. Bartholomew's were wiser men. The worthy alluded to was John Birch, Esq. surgeon to St. Thomas's.

Having the pen in my hand, I cannot avoid expressing some surprise at an opinion which seems to be gaining ground, that there is an identity between the two diseases, small-pox and chicken-pock—that varicella is only a modification of variola.

The period of infection—the first appearance and progress of the eruption—the variance of the inflamed base—the acuminated pustules in the one, the flattened pustules in the other—the difference of the fluid secreted—the manner of drying away of the disease, and the after consequences; all shew so much distinctness as, in my apprehension, clearly establishes two diseases.

Varicella seems to have been formerly a more severe disease than at present; or was rendered so by improper management; for the bills of mortality of the last century generally enumerated some deaths by it every year. The writer of this recollects to have attended several cases which created much alarm: one patient was with difficulty saved, and in one case death ensued. In both these cases, though the number of pustules was by no means excessive, several of them degenerated into black sloughs, with great general debility and exhaustion. One of the patients was the child of very poor and very dirty parents, who were unable and unwilling to do much for it; the other, which recovered, was the daughter of parents in a high rank of life.

ANALYSES & NOTICES OF BOOKS.

"L'auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

POISONING WITH COPPER.

Journal de Pharmacie et des Sciences accessoires, &c. Octobre 1832.—*Considerations sur l'emploi du sucre dans les empoisonnemens par les matières cuivreuses.* Par M. POSTEL, D.M.P.

THE paper, of which we are about to present our readers with an exact analysis, contains an account of some very important experiments performed by M. Postel, for the purpose of ascertaining the value of sugar as an antidote in poisoning with copper. Sugar has long enjoyed the reputation of being invaluable in this way: Marcellin Duval proved it by his experiments on animals; and Orfila, in the first edition of his Toxicology, confirmed its efficacy, as he also did in several articles contributed to the Dictionnaire des Sciences Medicales: he pronounced, in fact, that sugar, either in

the solid or liquid form, was productive of the happiest results in poisoning by copper. M. Orfila, in subsequent examinations of the chemical action of sugar on the acetate of copper, saw that it produced a rapid decomposition at the temperature of boiling water, disengaging the acetic acid, and leaving protoxide of copper, of an orange yellow colour. About the same time, M. Vogel proved that sugar exerted no chemical influence on verdigris except when the substances were brought in contact at 212 degrees; and that then protoxide of copper was disengaged, leaving some of the metal dissolved in the form of a brown liquid, in which ammonia could not detect its presence, but with which prussiate of potash formed a brown precipitate. How was it to be accounted for after this, that sugar could act as a counter-poison to salts of copper, when it did not decompose verdigris at the temperature of the stomach? The conclusion at which M. Orfila was induced to arrive was, that sugar did *not* act chemically on verdigris in the stomach, nor prevent it from acting corrosively, but that its utility was derived from its effect as soothing the injured parts after the poison was removed by vomiting. He and M. Bertrand, moreover, now proposed albumen as a proper antidote, in consequence of the property which this substance possesses of precipitating the oxide in solutions of salts of copper, and then combining with the precipitate, and producing an insoluble compound, destitute of noxious effects to the system.

M. Postel now took up the inquiry, and made various experiments both with sugar and albumen. By means of an œsophagus tube, he conveyed into the stomach of a dog a drachm of verdigris, dissolved in four ounces of water. And he did the same with another dog, of equal size and strength. Some instants after the introduction of the poison, the animals began to vomit, and passed some fæces, tinged with blue. M. Postel now introduced into the stomach of one of the dogs a large quantity of albumen, and into that of the other a large quantity of syrup. The vomiting and evacuations continued a little longer, but the animals became tranquil: they drank water which was set before them. The dog which got the albumen died in the night; and upon examination, the digestive tube and stomach were found considerably inflamed, with some ulcerations also in the stomach; but the other dog got well in a few days.

The experiment was tried a second time with the same result; but upon a third trial, matters turned out just the reverse: it was the dog which got the syrup that died, and similar lesions were found in his intestines. M. Postel's inference was this; that if, after poisoning with copper, animals be able to vomit, and have sugar or albumen administered to them, the chances of recovery are as three to two in favour of those treated with sugar.

Still M. Postel was puzzled about the cause, and was anxious to determine whether the sugar had not really the chemical effect on verdigris at the temperature of the stomach which MM. Orfila and Vogel found it to have only at the temperature of boiling water. He made several mixtures of verdigris and syrup, which he exposed to the temperature of 30° or 36° centigrade, (or 86° and 96° F.) and scarcely had he done so, when he perceived a remarkable change of colour, and presently after some points of reddish yellow. The latter tint soon became uniformly diffused through the mixture, and there was found at the bottom of the glass a powder of the same colour. In repeated trials he obtained the same results. He found, also, that if he used crystallized, instead of common verdigris, at the temperature of 36° cent. the result was the same, but the precipitate was of a deeper tinge. At the ordinary temperature, the same phenomena occurred, but not so quickly —the result required more patience.

He took a solution of pure verdigris in distilled water, and added a quantity of purified syrup, and then shook the mixture well for some time at the ordinary temperature: the result was, a precipitate, which was slowly formed, and of a deep red. The addition of larger quantities of syrup changed the colour of the whole mixture.

But what was the precipitate? Was it the same as that obtained by MM. Orfila and Vogel? M. Girardin, of Rouen, undertook the analysis, and found it to be protoxide of copper.

M. Orfila says that he always found animals to sink under a dose exceeding twelve or fifteen grains of pure verdigris; at least they could not resist its influence for an hour. M. Postel performed the following experiments:—

1. He injected 30 grains of crystallized verdigris, dissolved in 2 oz. of water, into the stomach of a healthy bitch; and shortly after, 4 oz. of powdered sugar dissolved in 4 oz. of water. He tied the gullet. The animal betrayed nothing unusual for twenty minutes, but then made violent efforts to vomit: some fæces were passed of a blue colour. In two hours the creature was manifestly sinking, and in three was dead. The carcass was stiff. The gullet, to within a short distance of the ligature, exhibited appearances of violent inflammation. The liquid in the stomach was of a bright green colour, but the viscus itself was not inflamed, except slightly about the cardiac orifice. The mucous membrane, however, was thickened and easily separated; the rest of the alimentary canal was normal. Nothing particular was observable about the trachea or bronchiæ; but the lungs were choked up, and the heart was full of clot. The uterus, which was impregnated, was strongly coloured with blue, as were also the placentas, which also were easily torn.

2. The same dose of verdigris was given to a dog, and afterwards four whites of eggs diluted with 3 oz. of water. The gullet was tied as before. The same symptoms of a strong tendency to vomit were observed as in the last case; the fæces were less blue; but the animal lived for five hours after the poison was administered. Upon examining the body twelve hours after death, the gullet was found red and inflamed; the stomach contained alimentary substances strongly tinged with green; the greater curvature was very red; the mucous membrane thickened, and easily detachable; but there was no other remarkable appearance about the viscus. Intestines sound. Lungs inflamed, full of blood, and easily torn. Cavity of the chest contained an abundance of clear watery liquid, and there was an albuminous layer, like false membrane, lining the serous tissue. Heart filled with clot of firm consistence.

Upon analysis, the substances in the stomachs of both animals shewed the presence of coppery salts: copper was even detected in the liquor amnii of the bitch.

The following are M. Postel's conclusions:—

1. Sugar decomposes verdigris, not only at the boiling point, but at the ordinary temperature; the decomposition is more or less rapid, according to the concentration of the liquids; and in both cases, the salts are reduced to the state of protoxide.

2. Sugar has a similar power in the stomach; for animals to which it has been administered last longer than those to which it has not; and the appearances after death are very different from those where there has been only the copper poison administered.

3. The changes effected by sugar and by albumen are nearly the same.

4. It ought, consequently, to be accounted an antidote to coppery poisons, inasmuch as it decomposes them, not only at the temperature of the stomach, but at the ordinary temperature of the air: besides that, it has been employed on many occasions with decided success.

Medical Botany. With coloured Figures. By Dr. Stephenson and Mr Churchill. Edited by Mr. Gilbert Burnett. Churchill, Princes-Street, Soho.

The numbers of this work for October, November, and December, are now before the public, and cannot fail to have made a favourable impression on those who have examined them. Each number contains four coloured plates—not of the kind often so called, which resemble nothing in nature—but well-executed, and, in some instances, highly-finished engravings. Some of them are really excellent: nothing, for instance, can be better than the representations of the Hyoscyamus Niger, and the Taraxacum. The Belladonna, too, and several others of the twelve before us, are beautifully executed. Each plate is accompanied with a botanical, chemical, and medical description of the plant, which is clearly and succinctly given, and followed by formulæ for its exhibition. The price is amazingly moderate (2s. 6d. per number), and the work deserving of every encouragement.

MEDICAL GAZETTE.

" Licet omnibus, licet etiam mihi, dignitaten *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."
CICERO.

FRENCH AND ENGLISH CHOLERA COMMISSIONS.

In the summer of 1831, when the cholera had fully established itself in the north-eastern parts of Europe, and appeared to be steadily advancing towards the south and west, two French and two British physicians were sent by their respective governments to Russia, to study the disease on the spot, and to communicate such information on the subject as they might consider best calculated to protect their countries from its ravages, by being made the basis of useful sanitary measures at home.

The objects and the destination of both missions were the same; the time of their setting out nearly so. The French physicians were chosen from the Academy of Medicine, the *élites* of the Parisian faculty—the British from such of the Army and East India Company's medical staff as happened to be in London at the time.

As both these embassies have published upon the St. Petersburgh epidemic, we have taken up their *Reports*, for the purpose of comparing them with each other, and of contrasting the conclusions at which they arrived; the data, as stated by themselves, upon which their conclusions were founded; and, finally, the results to which these conclusions appear to have led in their respective countries.

With respect to the French mission, we are informed in the preface to their report, that they were appointed medical commissioners to Russia in May; that on the 14th June, they were *en route* for Berlin, and that the whole code of their instructions was comprised in one sentence—short, indeed, but strongly characteristic—communicated to them by the Minister for Foreign Affairs:—" Follow," said he, " in every thing, the inspirations of your own intelligence and zeal!"

After an interview with Goethe, at Weimar, in which they endeavoured to borrow inspiration from " the intellectual king," by conversing with him upon the Madrepore islands of the South Sea, the mission traversed Germany, Denmark, Sweden, and Finland, (where no cholera was,) and at length arrived at St. Petersburgh on the 10th of August, two months after their departure from Paris, and nearly three months subsequent to their appointment. A patriotic aspiration is breathed, *en passant*, to the glorious recollections of Jena, Austerlitz, and Wagram. The poetic city of the north (Moscow, we presume, though the name be no where mentioned) is admired from the tower of the great Ivan; and the commission, after declining an invitation to the court of Sweden, returns to Paris in the spring of 1832, by Prussia, Austria, Bavaria, and Wurtemburgh.

Such is the programme of the journey performed by the French mission; and from the extraordinary circuitous route which they pursued, one can scarcely help suspecting, that they had a lurking hope that the disease might have ceased before they arrived at the place of their destination. It was known in Paris, long before the mission set out, that the cholera was at Riga: why, then, did not these gentlemen proceed direct to that place, through Lubeck, if the study of the disease was their sole or even their chief object? In this last city both missions might have met, and from thence proceeded together to St. Petersburgh. Very little explanation is given in their report relative to these

points, and this is the more remarkable, as we have seen that they were bound by no official ties, but left entirely "to the inspirations of their own intelligence and zeal."

The official reports of the British mission, on the other hand, are prefaced by no programme, nor do they afford any information, either as to the date of their appointment, or the events of their journey from London to St. Petersburgh and back; neither is there a syllable of poetry or pathos from beginning to end. We happen, however, to know that these gentlemen were first spoken to on the subject of their mission on the 17th of June, and that the next morning they were already on their way to Hamburgh, on board the steam-packet: and we perceive by the reports before us, that they arrived in St. Petersburgh on the 29th of the same month, just eleven days after their departure from London.

They appear to have gone to their work at once, for by their first letters we find, that on the evening of their arrival, they visited two of the earliest cases which had occurred, and had seen and examined eight others before the departure of their first despatch, dated July 1; accomplishing thus early one important object of their mission, by settling the identity of the Russian with the Indian cholera.

We shall now consider the conclusions of the two commissions *on the subject of contagion.*

One of the most important points connected with the investigation of any disease, viewed in its relations to public health, is the mode by which that disease is propagated. Accordingly, we find that this forms a most prominent subject in the communications of both commissions. But the conclusions respectively arrived at are diametrically opposed to each other. MM. Gerardin and Gaimard assert, that the cholera of St. Petersburgh was not communicable from one human being to another, either directly, by near approach, or indirectly, through the medium of inanimate matter.

Drs. Russell and Barry hold the converse of this proposition to have been clearly demonstrated at St. Petersburgh last year, by events which they themselves witnessed on the spot.

The French mission appeal to documents in support of their opinion, but we regret to observe that they allude only to such documents as are favourable to their own views. Our readers will judge for themselves.

The British physicians, again, send home their dry daily journal of the events which they had witnessed, giving dates, and names of persons and places; and although the non-contagionists in this country have thought fit to question their accuracy, they have not hitherto done more than shew that they felt the necessity, while they wanted the ability, to refute them.

It must be confessed, that the evidence appealed to on such occasions as the present, is but too often selected or prepared for a particular purpose; and its value must always be a good deal influenced by the character, the views, and the interests of the parties. It is, however, quite obvious that it cannot be necessary to send an embassy expressly to fetch documents which might as easily be forwarded by any other courier as by a medical commissioner; while, on the other hand, facts indiscriminately noted on the spot, can be had genuine only by actual observers and at the place where they have occurred: the nature, then, of the evidence which was sought by the English commissioners was greatly to be preferred, and, unless it can be shewn to be inaccurate, must be looked upon as infinitely more trust-worthy.

The leading document brought for-

ward by the French commission, was given them by Dr. Markus; being his history of the progress of cholera in a particular quarter of the Russian capital. Now Dr. Markus was a physician from Moscow, and editor of a medical journal in that city; in which, during and after the epidemic of the previous year, he most strenuously espoused the views of the party concerned in trade, as to the non-contagiousness of cholera, with reference both to persons and goods. By the merchants, Dr. Markus was sent to St. Petersburgh, in 1831, for the avowed purpose of supporting their views at the seat of government, and of leading the medical opinion of that city to a decision similar to that which he had been mainly instrumental in procuring at Moscow. He failed, however, in the object of his mission, the medical council of the capital having decided in favour of contagion, in the face of the Moscow Doctor and his documents, by a majority of not less than thirty-eight to two—Dr. Markus himself being one of the minority; so that he had gained only one proselyte.

Into the hands of this Moscow physician the French commissioners had the misfortune to fall, and from his statements, or papers furnished by him, almost exclusively, do they derive their information. The following are the grounds of their argument in favour of non-contagion:—

"Notwithstanding the most minute inquiries, the first persons attacked by cholera in the district have furnished no indication of the transmission of the disease, either by means of clothes or merchandize, or by communication with infected individuals. The temporary cholera hospital was established in a vast space, on a second floor, magnificently endowed, and provided with every thing necessary for the comforts of the sick. The elevation of the apartments, and a well-regulated ventilation, kept up a constant supply of pure air. The beds (fifty) were widely separated, and the most perfect cleanliness was maintained. There were treated in this hospital 119 cases, of whom 53 died. Of 58 hospital attendants*, one only was seized with cholera." (p. 35.)

From another document, furnished to the French commission by Dr. Seidlitz†, and forwarded to their government, it appears that, in the cholera hospital appropriated to the marine service, not one attendant, of 43, was attacked by the disease.—(p. 57.)

A third document is quoted for the assertion, that, of 44 persons attached to the Demidoff hospital, only two women and one apothecary were attacked; and MM. Gerardin and Gaimard conclude their History of Cholera Hospitals at St. Petersburgh, with reference to the communicability of the disease, in these words:—

"It would be superfluous to multiply quotations. If, to the importance of these facts collected in the hospitals, we add permanent activity on the part of the presiding physician, promptitude in the application of curative measures, and a continued zeal in the external treatment of this ever dangerous disease, we shall have all the positive notions which ought to serve as a basis for the formation of cholera hospitals."—(p. 58.)

From this extract, it would seem that the *three documents* which we have just mentioned as having been sent home by the French physicians, were considered by them quite decisive against the doctrine of contagion, and to be all that was necessary to guide their government in the adoption of sanitary measures.

At page 139, a statistical return of the cases and deaths at the Temporary Cholera Hospital of the Abrucoff is given, and signed by Dr. Schklansky, of that

* Supposing half the sick to have been in the hospital at once, a circumstance not very probable, the proportion of attendants would have been one attendant to each patient!!

† Dr. Seidlitz is the author of some Observations on the Epidemic of Astrachan, written to prove that cholera was not propagated by contagion in that city, in 1823.

establishment: yet, though the document is quoted and remarked upon at considerable length, not a syllable is said as to the number of attendants seized. In the detailed classification, however, of the cases (313 in number) treated for cholera in that hospital, from 21st June to 1st September, we find 12 *Gardes Malades*, but we are left to seek for information elsewhere as to whether these had been actually servants of the hospital or nurses sent in from other places.

How forcibly is the reflection here pressed upon our minds, that it is the solemn and sacred duty of medical commissions, not only to give scrupulously faithful details of the facts and documents which may have come to their knowledge, but also to seek for and record all evidence, with equal zeal on either side, touching that most important question—the communicability of the disease—which their country sends them to investigate.

We should naturally conclude, from the above extracts, that the attendants of many other cholera hospitals, besides those mentioned, had remained exempt from cholera during the St. Petersburgh epidemic, and that no examples whatever had occurred there of the contagious spread of cholera amongst that class of persons; else surely MM. Gerardin and Gaimard would have reported, instead of suppressing such facts; nor would they have left their government to the possible adoption of useless or improper measures, founded upon the faith of culpably partial statements.

Let us now turn to the official reports of our own countrymen, and see what they say with reference to the propagation of the disease amongst the hospital attendants.

"July 12th. Merchants' Hospital.—Superbly fitted up; some of the rooms small, and not freely ventilated.

"Attacked—one purveyor, two *feltchers* or barber-surgeons, four servants—one dead.

"13th. Hospital of the Semenoffsky regiment.—Attacked by the disease, three feltchers, seven servants—two dead.

"This hospital took in civil as well as military sick, towards the middle of the epidemic. The whole number admitted, three hundred and fifty-two.

"21st. Aboucoff Summer Hospital, converted into a temporary Cholera Hospital.—Servants attacked, eight—died, three.

"24th. Cholera Hospital at the School for the Sons of the Clergy.—Of eight servants employed, two attacked.

"August 9th. Hemp Merchants' Hospital—Of twelve servants employed, three attacked—two dead.

"12th. General Military Hospital, Vibourg quarter.—Physicians, three attacked—one died. Servants, twelve attacked—four died. Of twelve medical students employed *pro tempore*, all had diarrhœa and other slight symptoms.

"This hospital, at first purely military, and in the most perfect state of cleanliness and discipline (as, indeed, all the Russian military hospitals are), had few or none of its attendants taken ill. It was only after it had begun to admit civil cholera sick, and had become somewhat crowded, that the above casualties took place.

"14th. Naval Cholera Hospital.—Dr. Seidlitz, chief physician, states, that of forty-two attendants (two physicians), none were attacked. This hospital is composed of two detached buildings, standing in the middle of a field of about two hundred yards square, perfectly ventilated, and unembarrassed by other buildings on either side.

15th. Cholera Hospital of the Foundling Hospital.—Of forty-two attendants, fifteen were attacked, four feltchers included, of whom three were seized.

"Hospital for the Imperial Stables at St. Petersburgh.—Sick admitted, seventy-seven: of seven servants employed, three were attacked.

"Sept. 10th.—Rogistevensky Hospital, established in two inconvenient houses.—Physicians, five, and all the attendants of every description attacked*.

"Of two hundred and sixty-four physicians, the whole number in St. Petersburg during the epidemic, above forty

* This hospital is farther alluded to at page 79, and fourteen attendants enumerated who had taken the disease.—E. G.

were attacked by cholera, of whom nineteen died*."

The reader will perceive that two of the only three hospitals mentioned by the French commission, namely, those of the Abrucoff and the Marine, are included in the above catalogue, but that the hospital presided over by Dr. Markus is not noticed. In estimating the importance of this omission, it will be necessary to recollect, that Dr. M. being the avowed champion of non-contagion, and a violent partizan, unprejudiced information could not be expected from him, though otherwise a most respectable physician. This, however, is no excuse for the fact of the statement of his experience, whether correct or not, being altogether passed over; and the only circumstance which can exculpate our commissioners is, that we believe the hospital in question was established at a late period, and not till Dr. Markus' arrival from Moscow, so that the report of his observations, opposed as they were to those of his brethren, had not been made when Drs. Russell and Barry left St. Petersburgh, though they proved "a God-send" to the French commissioners, whose visit was considerably later.

Let us now give every reasonable degree of credence to the events recorded by the French from documents, and to those noted for themselves by the British commission, and what is the most rational conclusion for us to form as to the communicability of the disease? The answer will be found at page 92 of the "Official Reports;" and we must say, that to us it appears in no one respect overstrained, or such as is not entirely borne out by facts, which have not, and we believe cannot, be shaken:—namely, "That the epidemic of St. Petersburgh did not possess those absolute and indiscriminating communicable qualities attached to plague and small-pox; and that the risk of infection, incurred by the healthy who approached the sick, was in direct proportion to the want of cleanliness, ventilation, and space, around the latter."

In the foregoing comparison between the materials for sanitary measures transmitted by the two commissions to their respective governments, we have confined ourselves to the epidemic of St. Petersburgh, because it was there only that both had gone over the same ground. It is true that the French physicians did not arrive until after the disease had nearly ceased, having, as we have shewn, spent two months by the way, following "the inspirations of their intelligence and zeal"! For that, perhaps, we ought not to blame them, as it was not at variance with their instructions. But we cannot avoid smiling at the childish simplicity with which they formed their conclusions on so few and such slender data; and we know not which most to admire—the slowness of their journey, or the rapidity of their reasoning. We might speak in stronger terms of the manner in which they suffered themselves to be crammed by Dr. Markus, neglecting to inquire into the results at any, except two, of the hospitals established in St. Petersburgh; or, if they did inquire, suppressing the information they obtained, and transmitting to their government not one syllable of evidence concerning the northern capital, except what they derived from two physicians — the known and avowed champions of non-contagion.

If the suggestions of MM. Gerardin and Gaimard were adopted as the guide of the sanitary measures at home, and recent events in Paris and other parts of France be taken as the tests of their

* Some of the non-contagionists having called the accuracy of this statement in question, we applied for, and procured an official list from St. Petersburgh, containing the names and addresses of the physicians who had died, which will be found in a former volume of the Medical Gazette. —E. G.

influence and expediency, we shall only say that they afford some reason to doubt the "inspiration" of the commissioners.

ANATOMY.

A DEPUTATION connected with the meeting of pupils, to which we alluded last week, waited on Mr. Phillips, at the Home Office, a few days ago; having in contemplation to present a memorial to Lord Melbourne. We again repeat our warning: let public attention be directed to the subject of their complaint, and the evil in question will be multiplied ten-fold. The Bill has worked with astonishing facility, considering the very short period it has been in operation; and if those who have been most fortunate would but assist those who have been less so, and all parties would keep quiet, we are convinced that, in a very short time, there would no where exist any cause of complaint. The students have been urged on by a knave who said beforehand that the Bill would not answer, and is now trying various expedients to make good his words, which the results were quickly falsifying. *Since the riotous meeting referred to, the number of subjects has undergone a marked diminution.* He who makes appeals, addressed to the public, and tries to bring such questions into notice, is a professional renegade, and most treacherous to the cause of the students, whom he deceives by affecting to be their friend. The Secretary of the Home Department is in communication with the principal teachers, and we believe a little time and patience are all that are required to make the Bill work to the satisfaction of all parties.

DR. SPURZHEIM.

THIS indefatigable follower of Gall died last month at Boston, United States, of "brain fever," in the 58th year of his age. We know not on whom, if on any, his mantle will descend: but we hope nobody will be foolish enough to bring it across the Atlantic.

Dr. Spurzheim commenced his career about the year 1800: he joined Dr. Gall, and travelled with him over a great part of Europe, visiting gaols, schools, and every place which could furnish them with variety of human character: and about 1810 appeared their joint work on the Functions of the Brain. Dr. Spurzheim visited this country, but met with very limited success—little more than mere curiosity being elicited. In 1825, he again came to England, and gave lectures in the principal towns. He ultimately sailed for the United States, to try his fortune in the new world, and arrived at New York in June last.

CHOLERA.

IN London, cholera seems wholly to have subsided, and we understand that the Central Board of Health is to be immediately broken up. We regret, however, to state, that the disease has again made its appearance in Paris, and the various hospitals are once more receiving a certain number almost daily. The disease has also at length reached Norway, notwithstanding the utmost rigor of quarantine: it is remarkable, too, that in the opposite coast of Scotland, particularly at Aberdeen, the cases have recently become more numerous.

CURE FOR THE BITE OF A MAD DOG.

WE perceive that Sir Anthony Carlisle has addressed a letter to the *Times*, to announce his being in possession of a reputed remedy for hydrophobia: it has come to him, it appears, in sundry quart bottles, from the natives of South America.

HEREDITARY DEFORMITY.

A FRENCH lady (Mad. D.) has had twelve children—nine boys and three girls. One of the boys has a supernumerary toe on the left foot; another has six toes on each foot. The eldest brother, who has no superabundant toes, has six children: one of them has the additional toe. One of the daughters had a supernumerary finger on the hand; it was amputated when she was an infant. A sister of Mad. D. had several children; one of them had the supernumerary toe, she (the mother) being free from it.—*Gazette Médicale.*

SHOWER OF FIRE.

A SINGULAR phenomenon presented itself lately in some parts of France, particularly in the department of Orne, in the neighbourhood of Argentau. Several times, and during two whole hours, the atmosphere, which was calm, became filled with an innumerable quan-

tity of vivid sparks, forming a sort of shower of fire. The appearance was most striking between four and five o'clock in the morning. The same phenomenon was witnessed about Caen, where, however, it excited less apprehension than at Argentan, in which place the inhabitants were under the greatest terror. It is said that, in some places, the sparks were seen to alight upon the ground; but no traces of them have any where been found, and it is probable that the phenomenon really took place in the upper regions; the appearance of having descended being most likely an optical illusion.—*Ibid.*

NOTE REGARDING SCARPA.

In our memoir last week of this eminent surgeon, we should have stated more correctly that the danger which he most strongly urged to the recto-vesical method of lithotomy, was that of cutting one or other of the *ejaculatory ducts*; as may be seen from the following passage or two, from among many in his papers on the subject. "I cannot think that the recto-vesical deserves to be preferred to the lateral method, and that for these reasons: in the first place, it is impossible to cut the membranous portion of the urethra and the prostate vertically, without dividing the *ejaculatory duct* of the left, or perhaps the right, side; and, secondly, such a wound is constantly exposed to the contact of fæcal matter." And again: "Who can be sure, in performing the recto-vesical operation for the extraction of a large stone, that he shall divide vertically and equally the verumontanum, with such exactness as not to cut either of the *ejaculatory ducts?* &c."

GUY'S HOSPITAL.

To the Editor of the Medical Gazette.

Sir,

An accident unluckily arose respecting the signature to the letter treating on the experiments on Quinine and Morphia.

The author, who is Mr. H. Muson (*and not Mr. Roper*), being very much engaged, requested me to copy the above; which I did, and inadvertently signed my own name.

By inserting this note, or explaining more concisely its intention, you will greatly oblige

Your very obedient servant,

A. Roper.

December 13, 1832.

LECTURES ON CASES OF DISEASE,

Treated in the Dispensary of the University of London.

By Anthony Todd Thomson, M.D.

Jaundice—Intermittent Cephalea, the sequel of Cerebral Inflammation—Chronic Bronchitis.

Gentlemen,—Since I last had the pleasure of addressing you, we have witnessed the beneficial result of the treatment resorted to in a case of Jaundice, to which I directed your attention, on account of the obscurity of the cause.

Mary Lacy, the subject of this attack, an apparently healthy woman, aged 28, left Somersetshire to come to London about ten days before she was admitted a patient in this Institution. She says that she was in perfect health when she left home; that she travelled on the top of the stage, and thus caught a slight cold, but felt no other ailment. Two days after her arrival in town her skin acquired a yellow hue; she felt unusually weak, lost her appetite, and her bowels became costive. You saw, on the examination of the patient, that the skin, nails, and albuginea of the eye, were deeply tinged with bile: the tongue was furred, the pulse small and quick, and her expression was that of much anxiety. She described her stools as being nearly white, and the urine of a deep orange colour, tinging linen put into it. She complained chiefly of languor. Pressure on the region of the liver did not indicate any derangement of that organ; she felt no pain there nor elsewhere; had no sickness; she slept well; and the catamenia was regular. She had never been ill before.

From the history of this case no satisfactory idea could be formed of the cause which had led to the obstruction of the common duct, and the consequent retention of the bile in the hepatic ducts, so as to admit of its absorption into the circulation, and its suffusion upon the surface. As there was no pain in the right hypochondrium, even after taking food, there was no reason for thinking that a gall-stone had dropped into the common duct; and it was as difficult to imagine that inspissation of bile, sufficient to plug up the duct, should take place in so healthy a person. To what, then, are we to attribute the obstruction? It is more easy, gentlemen, to ask such a question than to answer it; and the only light that I can throw upon the case is, to suppose, from the absence of pain, and from the sudden manner in which the disease appeared in this young woman, that it is probable the resistance to the free passage of the bile

existed at the very extremity of the common duct, where it passes obliquely through the substance of the duodenum. We frequently find that opium, and other substances which cause torpidity of the intestinal canal, produce temporary detentions of bile, and white stools; and as frequently also, that the same effect is produced by defective chymification, if the food which passes the pylorus be incapable of affording a due stimulus to the duodenum. Now in this young woman, the length of the journey, the sitting for so many hours on a stretch, and a confined state of the bowels, may have acted on her, accustomed as she had been to active bodily exertion, in a manner similar to the foregoing causes, and produced such an atony in the ducts as to prevent the free passage of the bile into the bowels. I am of opinion that the orifice of the common duct resembles the pylorus in its functions; it requires the application of a certain stimulus to open it so as to permit the bile to flow.

Whether this opinion be correct or not, I informed you that, from the nature of the attack, the disease would not be of long duration, but would readily yield to medicine. The first object was to clear the stomach of crude undigested matters, not to force, as is generally supposed to be the result of an emetic, the passage of the common duct, by pressing into it the bile contained in the gall-bladder; but, by removing irritating matters from the stomach, to improve the character of the chyme, the natural stimulus of the common duct. For this purpose a scruple of powder of Ipecacuanha was ordered as an emetic; and this was followed up by eight grains of Calomel and six grains of powder of Colchicum, while a brisk purgative, consisting of Infusion of Senna and Tincture of Jalap, was directed to be taken on the following morning. My object in ordering the Colchicum was to aid the Calomel in its stimulant action on the orifice of the gall-duct, as I have had ample opportunity of observing the effects on the liver which always follow the administration of Colchicum; and I am of opinion that much of the benefit derived from it use is to be ascribed to this influence which it exerts on the biliary ducts. The result of these remedies was an evident improvement in the colour of the skin, and of the alvine discharges and the urine; but as the Jaundice continued for a week afterwards, although the Calomel, Colchicum, and purgative, were twice repeated, she was ordered to take five grains of blue pill every night, and three table-spoonfuls of the following mixture three times a day: in the morning, at noon, and at four in the afternoon.

℞ Sodæ Subcarbonatis, ʒij.; Ammoniæ Carbon. ʒj.; Decocti Aloës Comp. fʒvj.; Solut. Extracti Glycyr. fʒij. M.

In three days the beneficial effects of this plan were obvious; the skin and eyes recovered their natural hue; the tongue became clean, the pulse filled, the appetite improved, the stools were bilious, and, at the next visit, three days afterwards, the patient was discharged cured.

In judging from these results, it is evident that whatever was the original cause of the biliary obstruction, the liver had assumed a torpid state, and required to be roused to renewed action. This was effected by the excitement of the capillary system by the blue pill and the alkaline mixture; and the result has fully justified the treatment.

Intermittent Cephalea.

Another case of considerable interest is that of Elizabeth Haynes, who was admitted on the 29th November. The patient, you will recollect, is a woman of a pale, sallow complexion, much emaciated, and nearly exsanguineous. I find the following account of her symptoms in the case-book:—"Elizabeth Haynes, æt. 33, was confined seventeen weeks ago with a five months' child. Three days afterwards, although the secretion of milk was scanty, it suddenly left the mammæ, and violent pain of the head followed. She was bled with leeches and blistered between the shoulders, but with little relief. The head was then shaved and blistered, and this was several times repeated: she also took purgative and other medicines. A Spanish doctor, to use her own words, made an incision through the scalp, and applied caustic to the wound; but these means were productive of no beneficial effects. The headache still continues; she also complains of pain of the right hypochondrium; the bowels are irregular, the feet cold, there is occasionally great tightness across the chest, and she vomits almost every thing she takes into the stomach. The pulse is 108, small and intermitting; the evacuations are dark coloured and offensive; the urine is not high coloured, but deposits a pinky sediment. There is a regular exacerbation and remission of symptoms twice in the twenty-four hours. At three o'clock in the afternoon, chilliness, but not actual rigor, comes on, followed by severe headache, and then burning heat of the skin, but perspiration rarely succeeds; and the same symptoms recur at three in the morning. When she perspires she feels relieved. The following medicines were ordered:—

Applicetur Emplastrum Cantharidis, scrobiculo cordis.

℞ Calomelanos, gr. viij.; Micæ Panis, q. s. Pilula quamprimum sumenda.

℞ Misturæ Purgantis, ℥ij. horâ post pilulam capiendos.

℞ Quiniæ Sulphatis, ℈j.; Infusi Gentianæ Comp. ℥viij.; Acidi Sulphurici diluti, ℥j. M. Sumatur cochl. ij. majora, 2da quâque h rá inter paroxysmos.

She was also ordered an emetic powder, to be taken at the accession of the chilliness, should no improvement of the symptoms take place in forty-eight hours.

We have not seen the patient since the above plan was begun; but I have been informed that she is evidently improved; the sickness has abated; and although the headache still continues, yet it is much more supportable than before.

Now, gentlemen, the peculiarity in this case is, the intermittent type which an attack of apparent inflammation of the brain has assumed; for as I did not see the case in its commencement I can only form my opinion from its history; and looking at that, I should regard it as a case of metastasis, from the recession of the mammary secretion. The practice, in the first instance, seems to have been sufficiently active, and probably, but for the depleting measures which were adopted, the disease would soon have terminated fatally. It is difficult to account for its having taken on the periodic character; but it is thereby rendered more manageable; and I take this opportunity of impressing practical a truth upon your minds; that whenever an intermittent type is taken on, there is only one way of managing a disease, call it whatsoever name nosologists please:—it can only be cured by antiperiodic remedies.

The large dose of calomel was intended to allay the irritability of the stomach; and experience will teach you that there is not a more effectual method of effecting this, especially if at the same time its influence be aided by the counter-irritation of a blister on the scrobiculus cordis. With respect to the mode of prescribing the sulphate of quina, as an antiperiodic, some diversity of opinion exists. You will find that some physicians prefer giving a large dose immediately before the accession of the paroxysm; others adopt the plan which I follow, of giving it in more moderate doses at short intervals. I have subjected both methods to the test of experiment, and have found the latter most effectually to fulfil every indication for which the remedy is prescribed. In this instance the emetic was not taken; but, in general, its influence in breaking the catenation of morbid associations which keeps up the disease, is most striking and salutary. We have still to look after this case; and I have no hesitation in prognosticating a favourable issue.

If it be at all allowable to reason with respect to the nature of the affection of the encephalon in this case, as it did not come directly under our cognizance, I should consider it as a case of acute meningitis. The symptoms were violent headache, quick pulse, vomiting, delirium, but no convulsions—symptoms which point out the seat of the inflammatory action; for when the substance of the brain is the seat of inflammation, convulsions generally supervene, and the stomach becomes so torpid that frequently it cannot be excited even by the strongest emetics. But in making these remarks, I am willing to allow that any importance which might belong to them in this instance is much lessened by our not having seen the patient till the acute symptoms had subsided, and the disease had assumed the periodic character.

Chronic Bronchitis.

Many cases present themselves at this, as well as every other Institution of a similar description, under the name of "colds;" and which, from the frequency of their occurrence, and the slight nature of many of them, are little regarded. Some of the instances have lately, however, been of a more serious nature; and, as I have pointed out to you, gentlemen, some of them have displayed symptoms closely resembling those of humid asthma; others have been attended with these, which have led several of you to regard them as cases of phthisis: these are examples of that species of bronchial inflammation which has been so well described by Dr. Badham and Dr. Hastings under the name of Bronchitis. Those cases which have presented themselves here have belonged to the *chronic* variety of the disease.

The account which these patients give of themselves is that they have caught cold, and their constitutional cough, as they term it, has increased. On inquiry, you generally hear that they are liable to such attacks every winter. There is frequently some degree of dyspnœa, slight pain, or tightness of the chest, quickness of pulse, and other febrile symptoms, which increase towards evening; the digestive organs are affected, the tongue is coated, the bowels are irregular, and the cough is severe. In general there is no difficulty of expectoration; and in many instances the discharge of sputa is so copious as greatly to weaken the patient. It is in these last-mentioned cases that to an inexperienced observer the disease assumes the aspect of phthisis, especially when the sputa displays a muco-purulent character: often, in such cases, also, there is an evident hectic tendency, night sweats are complained of, and diarrhœa wears down the patient.

On inquiring into the causes of the at-

tack, it is generally referred to cold; but sometimes it appears to have followed, as a sequel, some other disease; and in a few instances it can be referred to the occupations of the sufferers. Thus, when the stone-masons were occupied on the columns of the portico of the University, several of them became patients of the Dispensary, owing to the dust of the stone entering with the air into the lungs. In these cases, the dyspnœa was much greater than that which you have seen in the instances lately before you. The greatest number of cases, however, is referred to cold. Now it is not cold, but sudden changes of temperature, whether from hot to cold, or from cold to hot air; but more generally it arises from entering hot rooms after long continued exposure to cold damp air. In these cases the abstraction of heat, or rather caloric, from the system is facilitated by the dampness of the air; the excitability of the system is thus so greatly augmented, that the reaction, produced by the elevated temperature into which the patient enters, is excessive, and inflammation is set up in the mucous membrane of the bronchial tubes, and this more readily from the existing state of that membrane and its predisposition to take on the inflammatory state. This effect of change of temperature is considerably increased by the use of ardent spirits, to which many of the patients who present themselves here are addicted. Among those who are thus affected, we seldom find cooks, and others who are much exposed to alternations of heat and cold; habit in them modifies the susceptibility of impression which others feel when exposed to the exciting causes which I have just enumerated.

If the stethoscope, or the ear, be applied to the chest in these patients, we find that a mucous rhonchus, as it is termed, is present, but not accompanying the whole of the respiratory effort; but although it is not universal over the chest, yet the respiration is not interrupted in any particular part of the lungs. Percussion does not detect any defect of the hollow sound, or resonance of healthy lungs.

When the attack is severe, or has continued for some time, and dilatation of bronchi has taken place, the most expert in the use of the stethoscope will find some difficulty in pronouncing with confidence on the absence of phthisis, or the presence of a tubercular cavity; and this difficulty is still added to by the fœtor which often affects the breath and taints the sputa, in dilatation of the bronchi.

In the treatment of these cases, you have witnessed the little benefit which results from the use of the lancet, and the great prostration of strength which often follows. On this account, I have relied more on large doses of Tartar Emetic than any other antiphlogistic means; and this antimonial, in conjunction with blisters, has constituted the chief part of the practice under your observation. When I say large doses of Tartar Emetic, I mean from one to two or three grains, according to circumstances, repeated every second or third hour. I have rarely exceeded three grains for a dose, for the best of all reasons—that it has effected all that I could anticipate from the use of the medicine. The first and the second dose usually causes vomiting; and this, perhaps, aids much the after influence of the remedy, by the impulse given to the capillary system by the act of vomiting. In severe cases, when it is requisite to maintain a counter-irritant effect on the surface of the chest, or between the shoulders, I have preferred the Emplastrum Calefaciens, or the Tartar Emetic ointment, to the perpetual blister, for fulfilling this intention; as experience has taught me that the common issue ointment, made either with Cantharides or Savine, although it excite more pain, yet is less beneficial than the suppurative irritants. From the copious expectoration which almost always attends these attacks, you will readily perceive why I so seldom employ expectorants; but when they are required, I have found a combination of the Oxymel of Squill, and the solution of the Muriate of Morphia, answer better than any other. Indeed the solution of the Muriate operates most kindly in allaying, not only the severity of the cough, but the general irritability of the system; and the slight constipating effect which accompanies its use becomes advantageous when the attack, as is often the case, is attended with diarrhœa. In the cases of Chronic Bronchitis which present themselves at this charity, there is seldom any necessity for ordering Ammonia as an expectorant; but you will have many instances in your future practice, gentlemen, in which—in severe cases, where the powers of life are depressed to an alarming degree, and suffocation is threatened—you must rely on this excitant as your sheet-anchor. It is often combined with antispasmodics, such as Assafœtida and the Gum Resins, and balsams; but I think that it is better to administer it in the simple state, in doses of from five to eight grains, sheathed with almond emulsion. These doses, repeated every hour, seldom fail to afford relief, if relief can be obtained by any medicine.

Tonics are sometimes indicated, after the violence of the attack has been brought down; and nothing is more useful, in such cases, than three or four grains the Sul-

phate of Quinia, combined with one-sixth of a grain of Calomel, and two or three grains of Extract of Conium, administered twice a day.

HOTEL DIEU.

CASE OF LUXATION OF THE LOWER END OF THE ULNA, WITH CLINICAL OBSERVATIONS,

By M. Dupuytren.

Luxation of the Ulna forwards without Fracture —Reduction.

M. Blot, aged 32, an officer of the Gendarmerie, of athletic form, was riding in the dark, when his horse took fright, wheeled round, and fell. M. B. being accustomed, as he said, to such accidents, disengaged himself from the animal in the act of falling. His right arm, however, got entangled, and was confined between the horse's head and the ground in such a manner as to receive a violent shock. He experienced acute pain at the time, and imagined that his arm was broken. Nevertheless, he gathered himself up, made a sort of sling for his hand, and walked home, leading his horse to Gisor's, a distance of nearly three leagues. M. Fournier saw him four hours after the accident, and recognized a dislocation of the cubitus. He had two persons to assist him, one of whom made counter-extension at the elbow, bent to a right angle, while the other pulled by the hand, the surgeon himself meantime endeavouring to effect the reduction by manual efforts. These attempts, continued for about half an hour, had no other effect than that of causing horrible pain to the patient. M. Fournier then ordered a bread poultice, with a view of allaying the swelling, which was now considerable, and withdrew. M. Dufay, another surgeon, who had in the first instance been sent for, arrived an hour after the above efforts had been made, and he now renewed the attempt at reduction, but without persevering very long. At nine in the morning, the two practitioners met, when they and their assistants made a strong pull, a long pull, and a pull altogether, but without any beneficial effect; and at the end of three quarters of an hour, they gave it up, and recommended him to go to Paris. Blot took their advice, and came to the Hôtel Dieu on the morning of the 23d of November, having travelled all night in a carriage, in which he declared that he suffered less than when he attempted to lie quietly in his bed. He presented himself at the consultation at ten o'clock, being thirty-four hours after the receipt of the injury. The symptoms were then as follow: —

The fore-arm was swollen; the hand in a positi n intermediate between pronation and supination; the inferior part of the fore-arm was rounded, and consequently lessened in its larger diameter; an unusual projection raised the skin at the middle and anterior part of the wrist; on the inner side the internal malcolus could not be felt; behind, a hollow occupied the situation of bulging usually produced by the head of the cubitus; if this bone was traced with the fingers from the elbow to the hand, it would be perceived that it was directed obliquely forwards and outwards, crossing and passing above the lower part of the radius. The dislocation of the ulna forwards was therefore evident.

The radius had remained in its place, and the hand followed this bone as in the natural state. The wrist neither projected forwards nor backwards. In making some movements, M. Dupuytren believed that he perceived an unnatural degree of mobility at the lower end of the radius, but without being absolutely certain of its existence; no crepitation could be detected; pronation and supination were completely destroyed; and, finally, two bruises were seen, one corresponding to the lower third and inner side of the ulna, the other on the outer surface, and at the union of the radius with the hand.

These points having been distinctly ascertained, M. Dupuytren proceeded to the reduction. The patient was seated at an angle of the wall, where there is fixed a ring, used for such operations; a sheet, which was passed under the right axilla, and through the ring, afforded a fixed point of counter-extension; another sheet was applied at the bend of the elbow, and given to the assistants in such manner that the fore-arm remained bent at a right angle on the arm; a napkin was attached to the wrist, and three assistants made extension. The reduction, however, was not thus accomplished. Perceiving the inutility of this mode of extension, it struck M. Dupuytren to extend the limb himself by the hand, inclining it strongly towards the radial side, whilst with his two thumbs united, he endeavoured to force the ulna inwards and backwards. By this means the reduction was accomplished. A slight noise was heard as the bone slid into its place, and the patient exclaimed, "I am cured." All the deformity had disappeared; the movements of pronation and supination were performed with freedom; the apparatus for fracture of the fore-arm was applied to guard against injury, and the patient sent to bed. He slept well the following night, and next morning the swelling had begun to decline. The bandages were re-adjusted; and in the course of the day he was again *en route* for Gisors.

Here then (observed M. Dupuytren) is one of those facts which you ought to seize and appropriate when they occur—for they are at once rare and important. I have looked through all my experience for analogous cases, and I have found but one. A builder, raising his hand to protect himself from a portion of wall which was falling upon him, had the wrist-joint dislocated, and came to the Hotel Dieu with all the symptoms of a luxation of the ulna forwards—such as we have seen in this patient. The reduction was accomplished in the same manner, and proved equally successful. Thus, reckoning that which is before you, here are the only two cases of the kind which I can call to mind as having occurred during the twenty-four years that I have been surgeon to this hospital. It is of importance that they should not be lost, for in surgery it is, especially with respect to dislocations, that precise details are wanting. If every author, in treating of this subject, had thought fit to speak of what he had seen, instead of copying the descriptions of others, we should ere now have had a multitude of accurate cases, which have been lost from negligence, while we should have been spared many of our present inexact and erroneous notions.

The skin, you perceived, was not torn. In the luxation of the ulna forwards, this, indeed, must be very rare, for it would require enormous violence to effect it; it would, in fact, be necessary that the radius should have been fractured severely, if indeed it were not comminuted, and the strength of the ligaments and the thickness of the fleshy parts, and even of the integuments in front, would present an impediment to external projection of the bone, which it would be very difficult to overcome. It is different with the luxations backwards—there the ligaments are not so strong; the bones are almost immediately covered by the integument, while the sharp projection of the styloid process forms a ready means of tearing through the parts. Have you not observed, after certain wounds from fire-arms implicating this joint, or its immediate neighbourhood, how, when chronic inflammation supervenes, the thin delicate skin about the outer and back part of the wrist becomes ulcerated? I have seen it perhaps twenty times; and it depends upon the projection of the styloid apophysis.

I have referred to the observations of Sir A. Cooper, and to those of M. Breschet; and I have looked into all the cases I have, and can only find two which are analogous. Now then comes this question: suppose there were dislocation with rupture of the integuments and protrusion of the bone—what should be done? Ought we to attempt reduction, or to cut off the projecting part, or to amputate? I would prefer immediate and exact reduction—making free incisions; for the chief danger lies on the side of inflammation and strangulation of the parts beneath the aponeuroses. I would not cut of the projecting bone unless the necessity for doing so were conspicuous; still less would I have recourse to amputation.

GUY'S HOSPITAL.

Strumous Phagedænic Ulcer of the Face.

Sarah Cobbins, æt. 36, of a sallow, unhealthy complexion, was admitted into Guy's Hospital, under Mr. Key, on the 12th of September, with a deep strumous excavated ulcer of the upper lip, of two years standing, which had extended to and nearly destroyed the septum nasi: had been under the care of a surgeon in the country during that time, but derived no benefit from the remedies which were employed. She was ordered on her admission Acid. Nitric. Dil. gtt. xl. ex Decoct. Sarsa. ter die sumend.; and the following lotion to be applied to the sore:—R Ext. Opii gr. v. Argent. Nitrat. gr. iij. Aquæ ℥j. M.—which treatment she continued to the 13th of October without any beneficial result. Subsequent to her admission, a small abscess formed on the anterior surface of the cartilage of the nose, which, on being opened, ulcerated, and destroyed a considerable portion of its substance.

Oct. 14th.—Ordered to continue the mixture, with the addition of 10 drops of the Acid. Nitric. Dil. to each dose; and to apply the following lotion to the sores:—

R Acid. Nitric.
Acid. Muriat. aa. gtt. xij.
Ext. Opii ℈j.
Aquæ ℥vj.

Under the latter treatment, the ulcer has rapidly improved up to the present time, and she is now (Nov. 30th) sufficiently recovered to be enabled to leave the hospital.

This woman had evidently suffered severely from syphilis; the throat had been formerly ulcerated and the velum injured. Her constitution was now in so impaired a condition, that mercury could not be exhibited, even supposing that the disease in the nose had a venereal disposition. Mr. Key, therefore, put her under a course of dilute nitric acid, which he commonly prescribes when mercury is indicated, but cannot be exhibited, on account of the

patient's general ill health. The effect of this remedy, together with the local application of the nitro-muriatic acid lotion has been most satisfactorily shewn in the progressive improvement of health, and the uninterrupted healing action of the ulcer.

Strumous Ulcers commencing in Ecthyma.

Susan Burford, æt. 18, admitted under Mr. Key, October 25th, affected with strumous cachectic ulcers on both of the thighs and legs, of three months standing. The patient is of an unhealthy exsanguineous appearance, subject to hysteria, and has had her catamenia absent four months. On her admission, the surfaces of the sores were covered by a thick brown incrustation, which being removed, exposed unhealthy indolent ulcers. The first remedies employed were a poultice, to remove the incrustations, and, internally, infus. cascarillæ, with carbonate of soda, bis die, and hydr. c. cretâ gr. ij. omni nocte, in starch. These remedies were continued till the 29th, when the sores became uncovered, and the following lotions prescribed.

Acid. Mur. gtt. xij.; Acid. Nitric. gtt. xij.; Ext. Opii, ℈j.; Aq. Puræ, ℥vj. ft. lotio.

This was applied to the right leg, on which were seated the deepest ulcers.

To the other leg the iodine lotion, consisting of

Iod. gr. ij.; Potass Hydriod. ℈j.; Aq. Puræ, ℥vj. ft. lotio.

At the end of a week the gums became affected by the hydr. c. cretâ, which gradually increased till November 12th, when it was thought expedient to administer the mercurial every other night only, being sufficient to keep the constitution under its influence. The lotions have been persisted in up to the present period, with the greatest benefit, all the ulcers having nearly healed.

In this case the action of the acid lotion was more beneficial than the iodine, the deeper ulcers cicatrizing as soon as the more superficial ones. It is also found, from extensive trials, that the two acids conjointly act with much more efficacy than the nitric singly.

These ulcers, at her admission into the hospital, bore the character of rupia, and the scabs had both the form and the dirty brown tint characteristic of syphilitic action; but on closely questioning her, there was no reason for believing that she had had any symptoms to warrant this suspicion. They were, therefore, considered and treated as strumous ulcers, and the mildest form of mercurial alterative, with alkali, and the cascarilla, were administered, according to the plan which Mr. Key usually finds most successful in treating this kind of sore. Increase of Burials, as compared with the preceding week * . . . . } 10·0

* This account is greatly increased in consequence of the clerks of the parishes of St. George Queen-Square, West Hackney, and St. Ann Westminster, having neglected to make their reports weekly, in due order, and having comprised in this week's report the whole number of burials which have taken place in those parishes during the past year: to the same cause may be ascribed the apparent increase of deaths by Cholera.

LECTURES

ON THE

THEORY AND PRACTICE OF MEDICINE;

Delivered at the London University,

By Dr. Elliotson.

DISEASES OF THE HEAD AND NERVOUS SYSTEM.

PHRENITIS.

Having concluded my observations, gentlemen, on diseases of the surface, I now proceed to consider those affections which are situated in the interior of the head. The first disease of which I will speak, according to the order I have hitherto pursued, is inflammation within the head, and which is called *phrenitis*, from φρην, the mind.

Symptoms.—In the first place you have the symptoms common to inflammation in every part, only that in this case they are situated within the head. There is a sense of constriction of the forehead, which answers to the sense of tension in other situations. You perhaps also have violent throbbing and pain in the head; throbbing in the carotid arteries, and vertigo; throbbing of the temples; throbbing within the head; throbbing at the back of the neck; and you have also an acute stabbing pain in the head, or a dull heavy pain. Although you cannot examine the part itself which is inflamed, you have morbid heat, and that heat extends to the external part which is not inflamed, so that you have another mark of inflammation—increased heat. Although you cannot see the part which is inflamed, and therefore cannot discern the redness, yet this frequently extends to the eyes, so that they are exceedingly suffused, and thus you have a third mark of inflammation. Three, then, of the marks of inflammation are to be observed, though not actually at the part itself. Swelling, of course, is out of the question. Besides the pain, there is what we usually notice in inflammation—morbid sensibility, extreme excitability of the mind, and intolerance of light and noise.

Another set of symptoms arises from a disturbance of the function of the part, so that there is general delirium, and it is not of a mild or slight character, but it is violent—*delirium ferox*. In the greater number of cases there is also constant watchfulness; the patient cannot sleep at all.

Then, as to the secondary symptoms which arise from sympathy, you have pyrexia—perhaps violent; you have a pulse accelerated, generally full, and perhaps also hard; at any rate, in the greater number of cases it is accelerated, and it is generally full and firm, if not absolutely hard. If it should so happen, that instead of violent delirium there is more or less stupor, then, possibly, you have a slow pulse, but in general you have violent delirium, and a full pulse. The tongue is of course altered in appearance—it is white. White is the usual colour of the tongue in active inflammation, and the tongue in this disease is generally white, but as the powers sink it becomes brown. Not unfrequently the stomach is affected, so that there is vomiting in the greater number of cases; and as the bowels become exceedingly torpid, there is likewise costiveness. The urine, of course, is generally high coloured. As the disease continues, it is by no means unusual to notice convulsions, and at last, perhaps, paralysis.

Now these symptoms may arise from inflammation of the brain itself, or of the membranes; and either of these affections is called "phrenitis." There are no distinctive symptoms in these cases. You will read in books that the pain is more acute,

and the pulse harder when the membranes are inflamed, as in the case of *arachnitis*; but that when the substance of the brain is inflamed, the pain is more of a dull character, and the pulse is not so hard. But although now and then you may make a very good guess, as to how it may turn out after death, yet I believe in the greater number of cases you will be wrong. In the majority of instances both parts are inflamed—the substance of the brain and the membranes; and frequently, when the membranes only are inflamed, there is not an acute, but a dull pain, and not a hardness of the pulse, but merely rapidity. Besides, too, the distinction is of no importance. The membranes are more frequently inflamed than the substance of the brain itself; and when the substance is inflamed, it is very rare indeed for the membranes not to be inflamed likewise.

It is said that when the superficial part of the arachnoid has been inflamed, there is usually delirium; but when the basilary part is affected, there is rather stupor and convulsions—at any rate, spasmodic movements. So that you see some would have a diagnosis between inflammation of the brain itself, and inflammation of its various membranes; and others go still further; and when the membranes are inflamed—at least the arachnoid, they would have us to infer that it is the superior part, if there be delirium, but that it is the basilary, if there be stupor and convulsions. This is the statement of some French writers.

Morbid Appearances.—After death you will find in regard to the membranes either a distinct red net-work, or an uniform redness, of greater or less extent. The minor degree, as I stated when speaking of inflammation in general, is where you can discover each vessel distinctly; and the higher degree is where there is uniform redness in any portion, because the uniformity of the appearance arises from the excessive number of vessels which contain red blood. These patches vary exceedingly in extent and frequency. It is probable, that of the three membranes of the brain, the arachnoid is the most frequently inflamed; and you may have the inflammation, not merely in the enveloping portion, but likewise in that which lines the ventricles. You know, of course, that the arachnoid membrane dips into the ventricles, and lines them; and either one portion or the other, or both, may be inflamed. When this membrane becomes inflamed, it is opaque, (that is a common effect of inflammation) and it also becomes thickened, which I likewise mentioned formerly to be a common effect of inflammation. There is generally a certain quantity of serum, either upon, or in the brain; and in the greater number of cases, as I mentioned when speaking of serous membranes in general, the serum is turbid. Not only, however, is the serum turbid, but often larger or smaller portions of fibrin are seen in it. Now and then the inflammation is so intense that layers of lymph are found either upon the brain externally—that is to say, upon the arachnoid, or in the brain—that is to say, in the ventricles. Sometimes the fibrin is not in the form of layers, but has a jelly-like appearance, and you will find this much the most frequent at the base of the brain. Now and then you will find absolute adhesions. In general death takes place when there is such violent inflammation too soon for the layers of fibrin to become adherent; but death may not take place so rapidly, the process may be slow, the inflammation may not be so acute, and then adhesions may be formed.

If the disease be rather chronic, this fibrin may become very thick and organized, and you may have it to a very great extent. I was shewn by a friend of mine a portion of fibrin which covered nearly the whole of the brain; and I should think that nearer a third than a fourth of it was an inch in thickness;—it was perfectly organized, forming an envelope to the brain. Pus is sometimes produced, and Dr. Baillie says that he once saw pus all over the surface of the brain, secreted, I presume, by the arachnoid. If it be the pia mater which is inflamed, this of course becomes red; there is more or less of fluid under it; and the fluid, from being confined under the membrane, like the vitreous humour in the cells of its capsule, gives exactly the appearance of jelly. The jelly-like appearance of the fibrin secreted by the arachnoid, of course lies upon the arachnoid; but the jelly-like appearance which arises merely from fluid collected in the pia mater lies under the arachnoid, the pia mater being within. When the pia mater is inflamed, you have, of course, redness of it; and now and then it has been said to suppurate, and even to have fallen into a state of gangrene. Frequently a very large quantity of blood is observed after this inflammation, between it and the cranium. The great turgescence is not confined to the vessels of the pia mater. Indeed, in inflammation of the head, the blood is not confined to the interior, but very frequently it extends to the scalp, so that you will find all the vessels of the scalp exceedingly full, and you will find an increased secretion in the scalp itself of serous fluid. When the inflammation of the dura mater is local, the effect of an injury arising either from a diseased bone, or external violence, you know that the superjacent scalp—the scalp immediately over the part, becomes so affected that it is quite œdema-

tous, and this is a point attended to by surgeons as indicating after an accident great affection at a particular spot within. In general, if the dura mater be inflamed throughout, there is a great turgescence of the vessels of the scalp, and a serous effusion into it; but if the inflammation be local, then you may have exactly over the spot an absolute œdema of the scalp.

When the substance of the brain itself is inflamed, you may have a very large number of red dots within, besides those which are always seen, and the latter may be double their usual size. You frequently, too, see a number of minute vessels—the vessels of the part, which ought not to contain blood, do contain it; and you see them in thousands, like so many fine red hairs in the substance of the brain.

Now and then the inflammation, when situated within the brain, runs on to abscess. This is most usually the case when the inflammation is not general, but local. Dr. Baillie says that he once saw the brain in a state of gangrene. I myself have seen the dura mater in that state, but I never saw the brain so; at least, if we are to judge of its existence from its being very lacerable and exceedingly offensive. From inflammation the brain will become exceedingly soft, so as to be a mere pap, something like very thick arrow-root and water. There are various degrees, of course, but still the brain is softened. Now and then you will see softened brain and pus together: the brain generally looks of a dead white colour, and of course the pus has more or less of a yellow tinge, but frequently they are seen together. It is very rare for the brain to become ulcerated on the surface, but now and then such a condition has been seen.

Now all these effects that I have mentioned are frequently observed after chronic inflammation of the brain as well as after an acute attack; and after chronic inflammation there is another effect very frequently seen, namely, induration in that part which has been inflamed. Acute inflammation generally causes, besides the redness, a great turgescence of the vessels, large and numerous red dots, distinct red vessels, a great fulness of the larger ones, perhaps more or less effusion, and perhaps abscess. But besides all this, in chronic inflammation the brain may become hard. Now and then acute inflammation may produce hardening, but I believe more frequently it is the effect of chronic inflammation.

When the substance of the brain has so been inflamed, and pus has been produced, it is sometimes not collected in a large quantity, forming an abscess, but it has been seen infiltrated throughout the brain, so that it has been found in the substance of the organ in innumerable points. Where this is the case, the substance of the brain is generally softened; because, in the first place, there must be a great degree of inflammation to produce pus; and when the pus is infiltrated so extensively, of course there cannot be induration. There is a great variety in the degree of this; so that you may have mere drops of pus in the midst of softened portions, and then still larger drops, till you come to such large ones that they are, in fact, abscesses. When the pus is collected in the form of an abscess, there is a capsule produced of various degrees of perfection, so that sometimes it has been known to have distinct coats. The contents of such abscesses will sometimes be exceedingly offensive; although, of course, no air could have had access to them. The parts surrounding an abscess in the brain may be in all states;—it may be perfectly healthy around the abscess, or it may be diseased and softened; it may be altered in colour, and so on. The matter of the abscess may, of course, remain there, and be found shut up all around; or it may work its way and burst into the ventricle, or it may burst into the nose, or into the ear. Abscesses more frequently occur in the hemispheres than in any other part.

Having made these minute observations respecting suppuration, I must make some equally minute respecting other changes. With regard to consistency, it is to be remembered that the firmness of the brain varies at different parts naturally; so that what would be morbid at one part would be only natural in another. It varies, likewise, according to the time at which we examine a body; a fresh brain being firmer than one some days old, and as soon as it is exposed to the air it becomes very soft. With respect to different parts, I need not say that the tubercula quadrigemina are exceedingly firm. The consistency, too, varies according to age: the brain of old people is firmer than that of young persons. There is a greater variety in the degree of change of consistency after inflammation, than in any other disease.

When the brain is softened, the part may retain its natural colour; or it may be yellow, it may be of a rosy hue, it may be grey, or it may be whiter than usual. If the change be not the result of inflammation, the part is generally exceedingly white; but the parts around, which are not yet softened, you will find rosy. But when the brain is softened, to say nothing of inflammation, the colour may be of all the varieties which I have just stated. It may be rosy from inflammation, or it may be perfectly white: the

redness being only in the surrounding parts. When the brain is inflamed, the softened parts may be mixed with pus, or they may be mixed with blood. If there be a vessel of any size very near, the blood is poured forth into the softened part. It is the grey part, some think, which is the most frequently softened; but, however this may be, every part of the brain is liable to it. When the membranes have been inflamed, it is the cortical part which is most frequently softened: from being in a bad neighbourhood, the brain under the inflammation suffers, and becomes softened. The softening may occur in one or more spots, and, like the existence of pus, it may be exceedingly partial, or it may be very general.

The spinal marrow, I may mention here, is liable to this softening just like the brain; and this softening occurs whether there is inflammation or not, and it is seen at all ages, but more particularly in old men. Generally around the softened part there is congestion and inflammation; very often you see inflammation, but frequently you do not: the part is frequently softened when no inflammation can be discovered. I recollect distinctly opening the brain of a young man whose brain was softened in a great many parts. He was not a patient of mine, but a medical man invited me to see him. He had had paralysis, and the brain was softened; but the part was so white that you could not conceive that there had been the least inflammation. I opened another individual shortly afterwards, where there were the most intense marks of inflammation—the brain was absolutely red around the softened part. This is a proof that, though these appearances are often connected with inflammation, yet they are sometimes wholly independent of it.

Then as to another change, the reverse of this—induration of the brain, it may, like softening, be very local or only rather local, or it may be general; and of course it varies very much in degree. Sometimes it amounts to no more than it would do if it had been hardened by acid; or it may amount to the consistency of wax; and now and then the hardness is still greater—it is of a fibro-cartilaginous character. When the brain is pretty generally indurated, it is said to be the effect of an acute inflammation; but, as I before observed, acute inflammation more frequently produces softening than hardening: however, in this case, hardening is more frequently thought to be the result of acute than chronic inflammation; but it is only the first degree of hardness—viz. that which is equal to the consistency induced by acids, which occurs from this process. When the hardening is general, you would not suppose that such extreme induration as to be called fibro-cartilaginous could exist universally throughout the brain; and such, indeed, is not the case. The second degree of hardness—waxy hardness—is usually local; and the same is the case with the fibro-cartilaginous hardness. This is exactly what we should *à priori* suppose. These two extreme hardnesses are almost always—perhaps always, but I cannot positively say so—the effect of chronic inflammation. It is said, that after fever and great debility—after a dissolution of the fluids and solids—but at any rate after great debility—the brain is frequently found in an indurated state; but I do not know this from my own experience.

Then, as to the red dots, they ought to be very numerous and very large—one, or indeed both, for us to say that there is morbid redness. You will find people differ every day about the inflammatory appearances of the substance of the brain; some contending that there are not more red dots than there should be, and others that there are. We therefore, I think, ought not to be satisfied unless there be a very considerable number, or they are of very considerable size. They are more usually found in the medullary than the cortical portion of the brain.

We must carefully remember, in examining the brain itself and its membranes, with the view of ascertaining the existence of inflammation, that position has a very great effect; that if the head lie in the usual recumbent posture, and the body is not opened till several days have elapsed after death, extreme congestion may take place at the posterior lobes of the brain; such as might lead us to suppose that there had been a vast accumulation of blood during life. If the body have become putrid, this congestion may amount to effusion; at least the slightest touch will cause blood to be poured forth. We should carefully note whether position has been capable of causing that accumulation of blood which we observe on opening the head. We must remember, too, that we ought to look at the brain the moment we cut it, because, after it has been cut and exposed to the air, it becomes rather redder than before. Our judgment should be formed, therefore, immediately on slicing the organ. It is likewise to be borne in mind, that both the brain and the spinal marrow, without any accumulation at either part, have a redder appearance when death has taken place rapidly, than when it has occurred slowly—that in sudden dissolution the brain and the spinal marrow are redder than in a chronic decay of the body. It is said,

too, that they are redder in persons who have been asphyxiated—who have been suffocated, or died from the want of air—than in other persons. We must also remember that the redness constantly varies in different parts—that there is more redness in the corpora striata than in many other parts. At the base of the thalami nervorum opticorum, there are naturally a number of red vessels, the appearance of which we must not mistake for turgescence. We must remember, too, with respect to colour, that the white part of the brain contains more vessels in early life than in old age, when it assumes a yellow hue, and has by no means the same number of vessels. We must remember, too, that the grey portion of the brain is much *more vascular*, as it is termed, than the white portion. When a part is redder than usual, there are not more vessels than natural—they merely contain more blood than they ought to do; and therefore the expression "more vascular" is, strictly speaking, incorrect; but we merely mean by that phrase that vessels contain red blood which ought not to do so, and that those which should, have an increased quantity in them. The grey part is generally more vascular than the medullary portion. All these things are necessary to be remembered, if you wish to form a nice judgment of the morbid appearances in the head.

In many states of the body the very reverse of all these appearances takes place. In some diseases the brain will become bloodless. In cases of starvation, it is said, that the brain will become colourless: this you may suppose. When persons die through the want of some natural stimulus to which they have become accustomed, there is also this extreme whiteness of the brain. I have seen this condition quite independent of a general cause, quite independent of the loss of blood, or the want of food, or the want of stimuli, but from local disease of the cerebral arteries. I have seen them diseased, so that they would not admit of a proper quantity of blood circulating through them, and the brain has consequently been rendered far whiter than it naturally is. However, this whiteness is said sometimes to occur after there have been signs of irritation of the brain, but I should think that it more frequently arises from the want of blood throughout the body, or causes preventing the brain from receiving its proper quantity of blood. So much, therefore, for the morbid appearances.

One of the most splendid books on the morbid appearances of the brain, is Dr. Hooper's: some of the plates are rather too shewy, but still they exhibit extremely well the appearances of inflammation. Representations of this affection are also given in Dr. Baillie's work on Morbid Anatomy, but the plates not being coloured, they do not shew it very clearly.

Causes.—Inflammation of the brain is less frequently an idiopathic than a symptomatic affection. It is more frequently seen as an accompaniment of fever than any other disease. It will arise, like any other inflammation, from cold applied to the body, especially when it is over-heated. It will occur also from simple heat; for if a person in a hot climate be exposed to the direct rays of the sun, without any covering on his head, especially if he be lying down, inflammation of the brain may be the consequence. This is called *insolation*. Sometimes instead of inflammation, apoplexy is induced, but this more frequently occurs if the patient make a violent exertion at the same time. Intoxication will produce inflammation of the brain. Spirituous or vinous liquors irritate the brain, or they would not intoxicate, and the irritation may amount to such a degree, that inflammation may occur. The same circumstance arises from mental irritation. Mental irritation, whether it arises from rage or anxiety, causes a great excitement of the brain. Want of sleep, or long-continued watchfulness, will have the same effect. Long continued excitement of a less degree may amount to the same thing as violent excitement for a short time. Excessive use of the brain cannot take place without the want of sleep and anxiety; no person studies without being anxious to learn what he studies, and his love of study induces him to sacrifice sleep.

Narcotics which stimulate the brain may also induce this condition of that organ. It is very common after large doses of opium, hyoscyamus, and stramonium, to find a throbbing in the vessels of the head. After a person has taken prussic acid, he may experience throbbing in the head, or throbbing of the throat, and more or less delirium. Wounds of all descriptions are common causes of inflammation within the head. Contusions, concussions, penetrating wounds, and mechanical injury of the head, may act in two ways, as exciting and as predisposing causes. You may have inflammation directly induced by them, or such morbid irritability excited, that any common cause afterwards applied, may easily produce inflammation; so that when a person has had injury inflicted on the head, whether it be fracture or any thing else, it is sometimes very dangerous for him to drink wine or beer, or spirituous liquors, for a very great length of time, or perhaps even to eat meat; for the least thing under these circumstances may cause

inflammation. This disposition will occasionally last for years. I recollect seeing a person, who, twenty years before, had suffered fracture of the skull, and on taking a glass of spirits, he immediately became almost delirious. I mentioned, when speaking of inflammation in general, that I had seen delirium induced from rheumatism of the scalp after an injury to the head.

Phrenitis has sometimes arisen from the cessation of an eruption. It is said that the cessation of itch has been followed by inflammation within the head; and sometimes it has arisen from the removal of a tumor. The tumor has taken off a great deal of excitement, it has required a considerable quantity of blood to nourish it, and the tumor being removed, there has been so much more energy throughout the system, and the brain has consequently suffered. This has more frequently occurred when the tumor has been situated on the head itself. This is exactly what we should suppose. Analagous to the cessation of an eruption is amenorrhœa, or costiveness. Women every day, from the cessation of the menses, when they ought to menstruate, become the subjects of violent headache, giddiness, and symptoms of that description. Now and then actual inflammation of the brain will take place. Costiveness every day induces headache; if a person pass his usual time for having a motion, headache takes place, and it is said that inflammation of the brain has sometimes been the consequence of mere costiveness. Inflammation of the eye, or the ear, or the nose, or the sinuses, will sometimes spread to the brain. Phrenitis has frequently carried off patients who have had nothing more at first than inflammation of the parts I have just enumerated. Of course, inflammation will spread in the head just as in other parts of the body. When the nose and the sinuses have been inflamed, in a great number of cases the bones have been found carious. I myself have several times seen phrenitis arise from disease of the ear. When a person has what is called *otorrhœa*, or *otalgia*—in common language, discharge from the ear, or earache—you ought to be on your guard to notice the first symptoms that he may mention of pain in the head, or the first anxious look that is displayed. The very slightest symptoms of cerebral affection, when there is a cessation of discharge from the ear, ought to put you on your guard. I have seen several cases of this description where persons have had phrenitis after pain of the ear, or discharge from that organ; some have had deafness, some have had pain formerly, and then only discharge. From having read on the subject before I witnessed these cases, I was on my guard. In the first case that I saw, there was a wildness in the person's look, and a quick pulse, and I expressed to the friends my belief that the person would never go out of the hospital again alive. You will find this circumstance mentioned by several authors, and several instances are quoted by Cheyne, in his work on Hydrocephalus. In these cases the bone is generally more or less carious. That portion of the dura mater spreading upon the petrous portion of the temporal bone, is found inflamed, perhaps softened, and perhaps there is pus there. I mentioned that I had once seen the dura mater gangrenous, and that was in a case of this description: the portion of the brain lying on the ear was likewise altered in colour—even underneath there was a very considerable change. In a short time the patient became violently delirious; no bleeding, no mercury could stop it; and for this simple reason, there was local disease keeping up the inflammation. There was diseased bone, and old ulceration within the ear; and you might as well have thought of curing inflammation while a portion of depressed bone rested on the head, or curing an ulcer where there was a piece of carious bone to come away, as curing this disease. It is not uncommon in venereal nodes, when the skull has become affected, for the dura mater to become inflamed, and the patient to die with all the symptoms of phrenitis.

When the external parts of the head are inflamed, as the scalp, or the face, it is very common for phrenitis to occur. When erysipelas of the face and head proves fatal, I believe in the greater number of instances it does so by inducing inflammation of the brain itself, or of its membranes; at least in every case of erysipelas of the head which I have opened, I have found very considerable effusion, either upon, or within the brain, or both. This is not an instance of metastasis, or the occurrence of inflammation in one part from its cessation in another, but it really appears to be an instance of the spreading of inflammation; for the inflammation of the face, and of the rest of the head, goes on just as vigorously in the greater number of cases when phrenitis has taken place as it did before it commenced.

Inflammation of the brain, however, certainly does occur sometimes in the way of metastasis. When rheumatism ceases in the joints, or gout ceases in some situations, phrenitis occasionally occurs; and it sometimes takes place after the cessation of inflammation in the salivary glands; in the case of mumps, or as it is sometimes called, *cynanche parotidea*. Phrenitis sometimes occurs immediately on

the cessation of this species of inflammation, but sometimes it occurs on the cessation of inflammation of the testicle, which itself occurs in the first instance after the cessation of inflammation in the salivary glands. Sometimes the testes are inflamed intermediately: it is very common after inflammation of the salivary glands for the testes to become inflamed; and when that inflammation ceases, phrenitis sometimes occurs; but sometimes inflammation of the brain occurs immediately on the cessation of the mumps themselves.

Phrenitis, however, as I before stated, is by far the most frequently seen as an occurrence in fever; and some may choose in this case to consider it idiopathic, excited by the contagion of typhus fever, or malaria, or remittent fever, or by excess, or vicissitudes of temperature. Some contend that fever itself, in many instances, consists of inflammation of the brain; and if they be correct, such phrenitis must be considered idiopathic. If, however, fever be a general affection of the system, then the phrenitis would be considered by those who hold that opinion as symptomatic. But these are mere differences of words.

Predisposing Causes.—Inflammation of the brain is predisposed to by native congenital irritability of that organ. Some persons have extreme irritability of the brain. If such individuals be thrown into apassion, or be suddenly and violently excited, they are very liable to phrenitis. Habits of intoxication, injuries of the head, all organic diseases of the head, and especially tumors in or upon the brain, necessarily have the same effect. All these things give a tendency to inflammation of the brain, so that an exciting cause easily becomes efficient.

OBSERVATIONS ON DYSTOCEA

FROM FAULTY POSITION OF THE CHILD.

Taken from Lectures delivered at St. Thomas's Hospital,

By Edward Rigby, M.D.

A FŒTUS which has been carried the full time of pregnancy can always be born as long as it presents with its long axis corresponding to the axis of the superior aperture of the pelvis. Oblique and transverse positions were first noticed by Van Deventer, a Dutch physician, at the beginning of the last century, and were said to be a chief cause of faulty position of the child.

The immense number of presentations which Baudelocque has described is the great fault of his work: a stuffed puppet was stuck into the pelvis in every manner that could be devised, and this was described as a peculiar presentation, and rules given accordingly how to proceed with the delivery, although many of these presentations never occurred in nature. Thus he enumerated actually seventy-four different species of presentation. How opposite is this to the plain practical observations of Dr. Denman! The presentation of children at the time of birth (says Dr. D.) may be three kinds, viz. with the head, the breech, or inferior extremities, the shoulder or superior extremities; the back, belly, or sides, properly speaking, *never* constitute the presenting part. Burton says, that next to the head presenting, the arm is more liable to offer itself than any other part. This is not exactly correct; but I deny that full grown living fœtuses ever present with the back, breast, abdomen, &c.; and I wish it to be understood that when I speak of a faulty position of the child, I mean where it presents with the arm or shoulder. Professor Nægelé, of Heidelberg, who, from being at the head of the midwifery department, is necessarily made acquainted with the result of every labour which is at all unusual through a very extensive district, assured me that of some thousand turnings which have occurred in the neighbourhood during the last twenty years on account of faulty presentation of the child, there have been perhaps one or two where the arm or shoulder has not presented: other presentations have, it is true, occurred, but only where the child was premature, or had been born dead. A child which has not been carried the full time, or has been dead for some days, comes *any how*: in the first case, it is too small to follow any peculiar course; it presents no resistance whatever; and therefore the form of the passages can have no effect in directing its progress: in the second case, a dead child, after a short time, becomes so soft and flaccid, from the loss of its vital elasticity, that it can be moulded by the uterus into any form whatever. If we read La Motte, Amaud, and others, we do not find a word of any other species of faulty presentation besides that of an arm or shoulder, except where the child was born prematurely, or where turning had been previously attempted by some awkward hand without success.

Baudeloque has considered obliquity of the uterus as one of the most common causes of faulty presentation of the child; but this opinion, once so prevalent, has been long since proved to be incorrect: the uterus towards the end of pregnancy is seldom perfectly straight, being almost always more or less inclined to one side of the abdomen, or is to a certain degree pendulous. The subject of obliquity of the

uterus belongs more properly to another species of dystocea; nor was Baudeloque right when he said that a faulty *inclination* of the pelvis as a cause of malposition of the child, for I know of a case where the pelvic axis was actually perpendicular, and yet the woman was mother of six children, each of which had presented with the head. He also considers a deformed state of the pelvis is a cause of mal-position of the child. When an author like Baudeloque asserts this, one would scarcely believe that in almost every case of the Cæsarean operation the child has been found with the head downwards, resting against the superior aperture of the pelvis, which was too contracted to allow it to pass. If deformity of the pelvis were a cause of malposition of the child, what difficulties would it not add to those cases where it is necessary to perform the perforation! and yet accoucheurs of the greatest experience will assert that they seldom or never met with a case where malformation of the pelvis compelled them to perforate, that the head did not present. Where Baudeloque enumerates an unusually large quantity of liquor amnii as a cause of faulty position of the child, I fully agree with him; for the uterus being so greatly distended, is not able to give that direction to the child's body which it does when there is merely the usual quantity. It seems more than probable that the first perceivable pains, or dolores presagientes, have a considerable share in determining the position of the child, for by the slight pressure which they exert, the long axis of the child is kept parallel with that of the uterus: as long as this is the case, the child presents either with the head or inferior extremities; but when the uterus is so distended, these forerunners of labour can have no effect upon the child's position.

Much dancing and jumping, and other species of violent exercise, have been assigned as causes of mal-position of the child; but I doubt much if this will have such an effect upon the manner in which the child presents. I know of a case where the woman was a rope-dancer, and exhibited at the various country fairs. She was brought to bed in the eighth month of her pregnancy, during which time she had been accustomed to stand almost as much upon her head as her heels, and to use the most violent exertions and contortions of her body, and yet the child presented with the head perfectly naturally.

The umbilical cord being twisted round the child's neck, or being unusually short, has also been assigned as a cause of faulty position of the child, but I know of no case to prove this: in fact, the cord is so often twisted round the child's neck, that I might almost say one half of the children are born with it in this condition. Cases, I own, do occur where it may be twisted so tightly round the child's neck as to cause its death, or where from this circumstance, or its being unusually short, the labour has been rendered tedious, (these will be considered in the third species of dystocea) but I know of no case where mal-position of the child has been produced by it. I am convinced that the position of the child depends very much upon the *form* of the uterus; and in this respect I am supported by Saxorph, Wigand, Boer, and Nægelé, four of the first continental *practical* authorities in midwifery. Thus Wigand, in a valuable work published after his death, says "that the original cause of faulty presentation of the child lies in the deviation of the uterus from its regular elliptical or pyriform shape." The first contractions, or dolores presagientes, are those which regulate the shape of it. Thus in a uterus for the first time pregnant, they generally act equally on all sides. Hence it is why in primiparæ the uterus is so exactly oval, and why we so rarely see faulty presentations.

"The first labour pains," says Fielding Ould, "which are very short, continue their repetition for two or three hours, or perhaps for more, before there is the least effect produced upon the os tincæ, *which time must certainly be employed in turning the head towards the orifice,* which being completed, the waters begin to gather." It is curious that this remark, made just ninety years ago, should not have attracted more notice; and Ould has the more merit, since until he published in 1742, scarcely any attention had been paid to the mechanism and other phenomena of labour. If the dolores presagientes act irregularly, or the uterus has a disposition to spasmodic affections of its muscular fibres, one side of it may be firmly contracted, while the other is quite loose: hence it will be drawn down unequally, and form a large pouch on one side. The result of this faulty configuration is that the position of the child becomes changed, so that its long axis does not correspond to the axis of the pelvis. On questioning women who have had difficult labours, on account of arm or shoulder presentations, they will almost uniformly tell you that during the latter part of their pregnancies they have suffered considerably from cramps and spasms at night time, and frequently describe the abdomen as being drawn into lumps. It is Professor Nægelé to whom I am indebted for the knowledge of this interesting fact; and I have had several opportunities since of proving the correctness of it. The following account, which he gave me, serves to illustrate this point very remarkably: it was the case of a woman who had

borne five times, and each time the child had presented with an arm or shoulder. Turning was of course necessary in every labour, and only two were born alive, and these unfortunately were afterwards carried off by the small-pox. Being pregnant for the sixth time, she was exceedingly anxious that if possible the life of this child should be preserved, and he was requested to attend her. He found her perfectly well made, but on inquiring into the history of her previous labours, he found that she had suffered extremely from cramps and spasms during the last months of pregnancy. Having tried opium by itself, or combined with ipecacuanha or valerian, without effect, he ordered her a starch injection, with twelve drops of tinct. opii every night as long as she continued to suffer from these attacks. The spasms soon ceased, nor did they appear during the remainder of her pregnancy, and my friend had the satisfaction of delivering her at the proper time of a living child, which presented in the natural manner.

Dead children, as I said before, are no rule for presentations, because they come any how. It is astonishing how quickly a child becomes soft after its death in utero. When it has been some little time in this condition, it becomes so closely packed into a round ball, by the general pressure which the uterus exerts on all sides of it, as to be truly surprising; so that, in trying to turn in such a case, it becomes very difficult to distinguish what we feel; for we find parts which in general are at some distance from each other, now in such close apposition as to completely mislead and puzzle us.

The signs of a faulty position of the child are various, and uncertain. Flatness of the abdomen has been considered to denote it; but this may alse shew the presence of twins, or of much liquor amnii. In thin subjects, where the head does not present, it may be felt sometimes externally through the abdominal parietes; but this is by no means uniform. In cases of eutocea where the head presents, it may be felt as early as the seventh month; hence in dystocea, from mal-position of the child, we shall not be able to feel it; but this is no proof of faulty position, for it may be a presentation of the nates: nevertheless, on examining per vaginam fourteen days before the woman expects to be confined, if we do not feel the head presenting, we should be prepared to suspect that all is not right. In a woman pregnant for the first time, it is a bad sign, for in these cases the head of the child lies remarkably deep in the pelvis during the last few weeks of pregnancy. Even under these circumstances our not being able to feel the head is no proof of mal-position, because it may be that the pelvis is narrow, and thus prevents the head from entering its cavity; or, as I have already observed, it may be a presentation of the nates, because the nates do not sink so deep into the pelvis as the head does. In women who have already had children, the head does not sink so low in the pelvis towards the end of pregnancy as in primiparæ. In cases where the woman has been pregnant so often as nine or ten times, the head is occasionally so high as scarcely to be reached by the finger, so that sometimes I have not been able to feel the head until the membranes had been ruptured, and then it seemed as if it were to come from a height. Nevertheless, it is a symptom which should put us upon our guard. "If on examination," says Dr. Merriman, "it should be ascertained that the os uteri is considerably dilated, and the child cannot be felt, this affords reason to suspect that the presentation is preternatural; should the liquor amnii be discharged, and the child be out of reach of the finger, the probability of a preternatural presentation is greater." Hence it requires us to be exceedingly cautious in forming our diagnosis; nor can we be quite certain until we are able to feel the arm or shoulder per vaginum. The power of distinguishing the various extremities and parts of a child can only be acquired by practice; it is impossible to describe these parts, for a description of their appearance gives no idea of their feel. Mad. La Chapelle has made a similar observation. A friend of mine, who is remarkable for the fineness and accuracy of his touch, was led to try the following expedient:—He tied the body of a still-born child in a large bag, and, cutting a small hole, introduced his finger to examine the presenting part; and he assured me that he had found great advantage from this method.

In a case of faulty presentation of a child, if nothing be done by the accoucheur, the arm or shoulder becomes gradually more and more wedged into the cavity of the pelvis. As long as the child is alive, the arm grows black, and swelled to such a degree that one would almost imagine it belonged to a child of five or six years old. If no assistance comes, the active pains gradually cease, and the uterus remains in a state of contraction amounting almost to a species of stricture; the whole abdomen becomes very tender, the pulse quick and hard, the skin dry and hot, the countenance flushed and anxious; the vagina will be found hot, extremely sensitive, and with no mucous secretion; in fact, all the symptoms of inflammation come on, which are quickly followed by

gangrene; or, during the height of a pain, the patient suddenly screams with intense agony: she complains of a sense of bursting or tearing within her; the pains cease instantly, followed by great prostration of strength; the pulse becomes small, and so rapid as not to be counted; the extremities cold; eyes glassy; the slightest pressure on the abdomen brings on acute pain, and death generally soon follows.

I need scarcely say that the symptoms which I have just enumerated are those of rupture of the uterus. When a rupture of the uterus, says Dr. Douglas, has really happened, it is generally marked by symptoms which are decisive; but from it being a case which occurs so rarely, they do not immediately create suspicions. When labour has continued violent a considerable time, if a pain expressive of peculiar agony be followed by a discharge of blood, and an immediate cessation of the throes, there is reason to apprehend this mischief. If nausea and languor succeed, with a feeble irregular pulse, cold sweat, retching, a difficulty of breathing, an inability to lie in the horizontal posture, fainting, or convulsions, there is still more reason to suspect the nature of the case. But if the presenting part of the child which was before plainly to be distinguished has receded, and is no longer to be felt, and its form and members can be distinctly traced through the parietes of the abdomen, there is evidence sufficient, I believe, to determine that the uterus is ruptured. The labour-pain, in consequence of which the rupture is supposed to have happened, is often described by the patient as being similar to cramp, and as if something was tearing or giving way within her. It has been said, likewise, to have produced a noise which could be heard by the people present. This brings me to consider what has been called the *spontaneous evolution of the fatus*, or that means which we occasionally observe nature adopts to expel a child which has presented with the arm or shoulder. This was first noticed by Dr. Denman, who was of opinion, that, in proportion as the head and upper extremities were gradually forced towards the fundus, by the continued action of the uterus, the nates had descended into the pelvis, and in this manner the child been born. Dr. Douglas, in a pamphlet which he published upon the subject in 1811, considered that Dr. Denman's view of the spontaneous evolution of the fœtus was incorrect, and that the arm and shoulder do not return into the uterus, but, with the side of the thorax, protrude through the os externum. Thus the side of the trunk comes to press upon the perineum; this makes room for the breech to descend from the brim of the pelvis into the hollow of the sacrum, and, by a few further efforts of the uterus, the rest of the body and lower extremities are expelled, leaving the head and one arm still to extricate. "If," says Dr. Douglas, "the arm of the fœtus should be almost entirely protruded, with the shoulder pressing on the perineum—if a considerable portion of its thorax be in the hollow of the sacrum, with the axilla low in the pelvis—if, with this disposition, the uterine efforts be still powerful, and if the thorax be forced sensibly lower during the presence of each successive pain—the evolution may with great confidence be expected."

The spontaneous evolution can only occur where the child is dead, and will seldom happen but where there has been delay in sending for proper assistance soon enough, or where the child has been dead some time. A case came to my knowledge of twins which had been united together by the breast, like the Siamese twins: they were carried the full time, and were by no means small children; for such a birth one would have supposed that not only the pelvis but the whole person of the mother must have been of larger dimensions than usual. I was never more surprised than when I saw the mother—a small, thin, delicate-looking woman. The children had been born dead, and this was the reason why so large a mass had been able to be expelled. I have no doubt but that the labour followed almost exactly the same course as the arm case which Dr. Gooch has recorded.

Dr. Douglas had several opportunities of observing the spontaneous evolution of the fœtus, and considered it so favourable, that he actually went so far as to think turning the child was unnecessary in these cases, for that it might be safely left to the powers of nature; but this cannot hold good in practice, for it is exposing the child to certain death, and the mother to the most imminent danger: there is no doubt that in cases of very difficult labour, the spontaneous evolution of the fœtus is a most fortunate occurrence for the mother, but *not* for the child.

But to return to the treatment of a case where the arm or shoulder presents. It has been supposed, that when the head is high above the pubes, we might guide it into the pelvis, or towards the fundus, by pressing upon it externally through the abdominal parietes. Wigand, of Hamburg, tried this practice, and Dr. W. Hunter used a similar plan when he tried to turn the fœtus with the nates into the pelvis. The most important complications of faulty position of the child are, with a contracted pelvis, or stricture of the uterus: by stricture of the uterus, I mean that vio-

lently contracted or almost tetanic condition of the uterus which not only renders the child immoveable, but makes it almost impossible to introduce the hand for the purpose of turning: this latter complication is by far the most dangerous. Where the liquor amnii has escaped some time, it increases the danger and difficulty immensely; the uterus contracts tightly upon the child, and inflammation, and rupture, &c. are apt to follow. Suppose, for instance, we are sent for suddenly to a case of this sort: on arriving at the patient's house, we find the liquor amnii has escaped some hours since; the arm in the vagina quite livid, and so swollen as to prevent our introducing the hand to search for the feet; the uterus is hard, contracted; and the least attempt to pass up the hand produces intolerable suffering, or perhaps even convulsions; moreover the accoucheur by whom we have been sent for, informs us that he has already tried to turn, but without success. What are we to do?

Bleeding is here a *mighty* antispasmodie, and is most strongly and imperatively indicated. I have known of several cases where it was impracticable even to introduce the finger between the child and passages, and yet after the relaxation, or even syncope, produced by a full bleeding, the hand has been introduced with comparative ease, and the turning completed. "Bloodletting," says Dr. Dewcess, "is the only remedy with which we are acquainted that has any decided control over the contracted uterus: it is one almost certain of rendering turning practicable under such circumstances, if carried to the extent it should be. A small bleeding in such cases is of no possible advantage, for unless the practitioner means to carry the bleeding to its proper limits, which is a disposition to, or the actual state of, syncope, he had better not employ it." Nature herself clearly points out the necessity of active and decided bloodletting, to relax the uterus and external parts. "The vagina," says Wigand, "is never so soft, so dilatable, and capable of admitting the hand, as during the presence of an active hæmorrhage; and this is equally the case in primapara as in those who have had several children;—and it is a mistaken kindness in the medical attendant who, in order to spare his patient's sufferings under these circumstances, delays to introduce his hand until the hæmorrhage has ceased. The moment this is the case, the vagina regains more vitality, sensibility, and power of contraction; the hand now experiences much more opposition, and excites far greater pain than during a state of syncope." My father, in his Essay on Uterine Hæmorrhage, makes a similar observation.

Besides bleeding, we should also try the warm-bath, and neglect no means by which we may calm the mind of our patient; for this is of great importance. To diminish the spasmodic action still further, an opiate injection will be advantageous. In the state of vehement contraction in which the uterus was before the bleeding, turning was not merely impossible, but *contra*-indicated; for attempting, under such circumstances, to turn, we should have run a considerable risk of rupturing the uterus.

When the arm presents, the accoucheur must not lose time in endeavouring to reduce it: he must slide his hand into the uterus by the side of the arm, and bring the feet into the passage; the arm, by that means, will go in again of itself. "An arm presenting," says Chapman, "and advanced as far as the arm-pit, is *not* to be returned; but the hand is to be introduced (which, as Deventer justly observes, is often found to penetrate with much more ease when the arm hangs down than when it is thrust back again) and the feet to be sought for; which, when found, the arm will prove no great hindrance in turning the child." It is in no case necessary, or in anywise serviceable, to separate the arm of the child previous to the introduction of the hand of the operator. "In some cases," says Dr. Denman, "to which I have been called, in which the arm had been separated at the shoulder, I have found it a great inconvenience; there being much difficulty in distinguishing between the lacerated skin of the child and the parts appertaining to the mother: the presenting arm is never an impediment of any consequence in the operation, and therefore need not be regarded, or on any account removed."

Although, after all our attempts, it be still impossible to introduce the hand to turn the child, the case nevertheless still demands that the woman be delivered. Nothing remains now but recourse to cutting instruments: we must perforate the chest with the Smellie perforator, and, having made a sufficient opening, must bring away the viscera. This will generally give us sufficient room to pass the hand; if not, we must try to bring away portions of it as well as we can. This is no case for the Cæsarian operation; the system is too much exhausted, and the parts too much inflamed, &c. to admit of it.

These extreme cases rarely happen in lying-in hospitals, or in large cities, but in the country, remote from assistance, and where an ignorant midwife has made the case much worse by pulling at the arm. Mad. la Chapelle's admirable observations

upon this subject deserve your attentive perusal. The *pravus fœtus situs*, the vicious, faulty, or mal position of the child, has not been sufficiently treated on by authors: it has never been made the subject of a distinct monograph, but has merely been cursorily discussed under the chapter of turning. Some authors have described a presentation of the head and arm *together:* thus La Motte, in his eighty-fourth observation, gives a case of this sort which terminated by the natural powers; and if I recollect rightly, Dr. Ramsbotham has recorded a similar case. I know of one case, but whether the midwife had been pulling at the arm or not, it is difficult to say: at least she denied it. It is extremely common to have a hand come down by the side of the cheek, nor does this produce the least hindrance to the passage of the head. In a practice of several years, one meets with complications and irregular cases which are sometimes not even described in books. Thus, for instance, Professor Naegelé told me of the following case: it was a case of first labour, and the head was passing over the perineum when he remarked a discharge of blood from the anus: he examined, and about three inches up the rectum he felt an elbow of the child protruding: it had somehow come down along with the head, had become entangled in the vagina, and forced its way through into the rectum. When the child was born, he examined the vagina, and found a laceration of the posterior wall, corresponding to where he had previously felt the elbow in the rectum. He was at first uneasy about the case, fearing that she would not be able to retain her fæces. He gave her a laxative, and kept her quiet. In two days after labour, he found the laceration, which at first seemed so extensive, surprisingly contracted, and on the 12th it was completely healed. This was evidently a complicated presentation of the head and arm, and belongs to those cases which are among anomalies of the rarest description: nevertheless, it is necessary.

As to the complications of the head with both arms, we have *no* example of it in the experience of our great practical authorities in midwifery, as Mauriceau, La Motte, Smellie, and La Chapelle: it only exists in the copper-plates of certain works on midwifery. Nor can the position of the child exist in nature where the feet and head are wedged together in the pelvis; but I will not deny that it can be *made* during an unsuccessful attempt to turn the child: in this case the feet may have been even pulled down into the os uteri, and yet the head has not quitted the pelvis. When called to a case of this sort, what are we to do? The accoucheur tells us he has made several attempts to turn, but could not succeed. The first thing to be done, as the system is more or less excited, is bleeding, followed by warm fomentations to the abdomen, and an opiate injection; then try to pass a noose round the feet, and when this is done, we may safely push up the head, and the feet will soon descend.

AN ESSAY ON FEVER.

By Thomas Spence,

Assistant-Surgeon, 52d Regiment.

Fever is a state of vascular and nervous excitement of the system generally, with or without determination to particular organs, suspending certain secretory functions, whereby the quantity and quality of the blood is changed, and rendered both chemically and mechanically unfit for the purposes destined by nature.

On the authority of nosologists, there are many varieties of fever, and in books they are found to follow each other in the most systematic order, and the student naturally imagines from the precision with which they are distinguished on paper, that they are each separate diseases, arising from opposite causes, being marked by distinct characters, and differing in pathology. Nature however discloses that each may arise from any one cause, that in the same person all the different forms are assumed, and that the pathology is generally to be found in the same organs; thus, chameleon-like, a patient may be seen at different times by a number of practitioners, and each will denominate the disease differently. One day it shall be a continued, another a typhus, the third a yellow fever, and, lastly, it may assume either a remittent or intermittent character.

The causes of fever are various; many of them easily traced, being cognizable by our senses; others are with more difficulty understood, being only known by their effects: amongst the former may be enumerated, heat, cold, moisture, fatigue, mental or bodily excitement, pain or local irritation, indigestible matters taken into the stomach, and putri-

fying or vitiated animal matters introduced into the circulation: amongst the latter, are malaria, and marsh miasmata. It is difficult, perhaps impossible, to demonstrate rightly the *modus operandi* of these causes in developing fever; but if I am not mistaken, the first impression of the majority is received by the nervous, and acts through it, upon the vascular system. This action, according as the agent is depressing or exciting, operates either by diminishing or increasing the force of the circulation; that is to say, the nerves receiving the shock of a depressing agent—for instance, an accident—immediately suspend or interrupt the powers of the circulation, whereby the blood is retarded in its progress from the internal parts to the surface of the body, the consequence of which is, coldness of the extremities, vertigo, nausea, difficulty of breathing, feebleness of the pulse, and sometimes vomiting; this state passing off, either by the struggles of nature or assistance of art, a re-action takes place, which excites preternatural quickness of the heart's action, and propels the blood with increased celerity through the vessels, whereby a quantity of caloric is evolved, which causes an expansion of the particles, and probably some important chemical change in the component parts of the blood: this state of excitement may be produced directly in cases where the cause is an irritant, for instance pain. The alteration then in the quantity, quality, and quickness of the circulation of blood through the secreting organs, is incompatible with the due performance of their different functions, the suspension or unnatural operation of which must necessarily leave to circulate through the system many matters which are of a deleterious nature. A moment's reflection is sufficient to convince us of the injurious effects certain to follow suppression, even for a few hours, of the secretion from the kidneys and skin. It is clear that besides the saline and other elements entering into the composition of urine and perspiration, a very great addition of fluid must necessarily remain in the circulation. Then again, if the elements composing bile be not duly separated from the blood, a train of evils succeed, which affect the constitution most powerfully.

The brain being an organ through which an immense quantity of blood is constantly passing, becomes materially affected by the increased quantity of the circulating fluid, and the bones of the head not yielding in proportion to the augmentation of fluid to be contained in the cranium, compression to a certain extent takes place. The liver, stomach, and bowels, besides suffering from the preternatural quantity of blood thrown upon them, are also sympathetically affected through the brain. The intimate connexion between these organs is a fact so well established, that to allude to it is sufficient for my purpose.

Thus, then, we have set up in the system, either directly or indirectly, a state of fever in which the quality and quantity of the blood are changed, and its circulation quickened; in which the nervous system is disturbed at its very foundation, and the functions of various important organs suspended.

We find that these internal changes are accompanied by corresponding external symptoms, which are certain evidences of the pathology: they are, a dry heated skin, a flushed countenance, suffused eye, quick full pulse, headache, pain in the back, weariness of the limbs, foul tongue, sickness at stomach, disordered bowels, and scanty high-coloured secretion of urine. This I look upon to be the simplest form of fever, which, being once established in the system, will be mild or severe, short or protracted, according to the remedial means adopted, and to the state of the internal organs at the time of attack; for it is well known that the body will receive a shock with impunity at one time, under which at another it would suffer severely. The predisposition of the constitution to disease will be found to depend very much on the habits, age, and temperament, of the individual, and also upon the climate wherein he resides; in a cold climate the lungs, and in a warm one, the liver and bowels, are most predisposed. It rarely happens that febrile excitement is established for any length of time in any constitution, without one or other of the vital organs becoming implicated: as few, indeed, are the individuals who have not some latent weakness. The symptoms will vary in proportion to the degree of the local determination, and to the importance of the organ attacked.

The brain, either in its substance or membranes, is often the seat of inflammation in fever; the evidence of which is pain and heaviness of the head, the dull and glazed appearance of the eyes,

the contracted pupil, and intolerance of light and sound, the concentrated heat of the scalp, restlessness, deprivation of sleep, and delirium.

The substance of the lungs and pleura may be implicated in persons predisposed, of which the cough, pain in the chest, and hurried laborious respiration, are clear indications. When the mucous membrane of the bronchiæ becomes inflamed, a marked change takes place in the symptoms of the fever, and those appear which have been termed typhoid. The peculiar influence of this affection was long since demonstrated by that enlightened and ever-to-be-lamented pathologist, Dr. Armstrong, who, with Mr. C. Haden, Mr. Alcock, and some others, have the merit of having directed public attention to this important discovery. The indications of inflammation of the mucous membrane of the bronchial tubes, are a brown dry tongue, (which, even when most moist, is covered by a thick glutinous secretion), the complexion becomes of a livid or leaden hue, the lips, instead of being red, are almost black, and, with the teeth, are covered with sordes; there is a remarkable depression of the vital, and disturbance of the mental power. These symptoms are easily explained by a reference to physiology: the tenacious matter seen on the tongue likewise lines the air-passages, and prevents the atmospheric air coming duly in contact with the blood, and chemically purifying it. The stomach, liver, and bowels, are implicated directly or indirectly in every protracted case of fever, bearing however a more conspicuous part in some than in others, and will especially be observed where the fever shall have arisen from malaria. The evidence of these viscera being affected is often obscure, and can only be perceived by close observation; indeed it has too often been overlooked altogether, until the secret was exposed after death, by inspection. I fear also that there are many practitioners who, even in this last investigation, rarely think of looking for this morbid anatomy, and many are the examinations in which the ulcerated mucous membrane is never exposed. The mucous membrane of the stomach is particularly liable to inflammation in fevers occurring in a tropical climate, and forms a most distressing part of the complaint: its existence may be ascertained by the constant vomiting, pain in the epigastrium, and red tongue. The irritability of the bowels, pain on pressure, and heat of the abdomen, and the smooth, dry, red tongue, are symptoms of the inflammation of the mucous membrane of the small intestines. In some cases there is the additional testimony of copious discharges of blood by the rectum. The disorder of the liver in fever is generally functional, and may be ascertained by investigating the alvine and urinary evacuations: in some instances (particularly in warm climates), the conjunctiva is tinged, and the skin jaundiced, which in these climates has been considered sufficient to stamp the fever with a new name, and thus we have a yellow fever, but in truth, it is only an additional symptom, and yellow fever and bilious fever are one and the same.

The symptoms then of fever occurring in a healthy subject, where there is no pre-eminent local determination, are headache and giddiness, with languor and a sensation of chilliness over the whole body, nausea, loss of appetite, pain or aching of the back and limbs, urgent thirst, foul tongue, heated and dry skin, full and quick pulse, the sleep being disturbed by starting and frightful dreams, the urine scanty, high coloured, and scalding the urethra in its passage, with much disorder of the bowels.

If seen early, the treatment must be vigorous and prompt: it consists in a free abstraction of blood, which must be taken, for the purpose of diminishing the vascular distention, and therefore it is desirable to obtain a certain quantity, if possible. In inflammatory affections this operation is performed under different circumstances, and it is then of importance to produce syncope; but this effect in fever ought rather to be avoided, and therefore when its approach is indicated by the pulse, the patient had better be placed in the recumbent posture, and the flow of blood stopped for a few minutes: by these precautions there will be little difficulty in obtaining a sufficient quantity, and from 16 to 30 ounces may in the majority of cases be taken with advantage: to this rule, however, there are some exceptions, and it sometimes happens that persons of apparently robust constitutions are, in an attack of fever, incapable of sustaining even the most trifling loss of blood; but to these peculiarities I shall hereafter more particularly allude. Having, then, by bleeding, removed the pain, weight,

and giddiness from the head, and diminished the force and frequency of the pulse, an emetic of ipecacuanha and tartrate of antimony should be administered: this is generally a most powerful and efficient agent, in the treatment of fevers; it produces considerable relaxation of the whole system, diminishing the force and quickness of the heart's action, and often exciting copious perspiration, always a desirable object, and further it occasions an abundant secretion of bile. The effect of the emetic having subsided, no time should be lost in the administration of eight or ten grains of calomel, followed by salts and senna, which, besides restoring the secretions, and thereby purifying the blood, removes irritating matters from the alimentary canal, and by its purgative influence depletes the system. Thus, then, in the space of a few hours the disease is attacked by a formidable force, to which it generally yields; occasionally, however, it happens that the means adopted are less successful; and at the expiration of a short time the patient may again labour under headache, the skin be dry and hot, and the pulse have become again full, hard, and quick; under which circumstances, particularly if the bowels have been freely acted upon, I seldom hesitate to bleed again to the same extent, and repeat the purge. If after this the headache, or pain in any organ, should remain, a dozen or two of leeches applied to the temples, or part affected, will be found very serviceable, followed by a blister, and a continuation of the purgatives. In conjunction with these agents, the strictest antiphlogistic regimen, and the recumbent posture, must be maintained; tea, or toast-water, is all it is necessary to give. The apartment should be kept cool, clean, and well ventilated. This treatment, as I have said, will for the most part check the progress of fever, and in a few days the patient will be fit for duty; but in some instances it assumes what is properly called the continued fever: continued, indeed, it is, and will be, in spite of medicine or medical means. From much observation I can confidently assert, that this protracted form of fever depends entirely upon inflammation and ulceration of the mucous membrane of the small intestines, particularly the ileum. My attention was first directed to this circumstance at the London Fever Institution, where I had an opportunity of attending throughout the course of my professional education, and saw no case in which, both before and after death, it was not a most prominent feature; since then it has been my lot to witness fever both abroad and at home, and I never examined a case of continued fever in which there was not inflammation of the small intestines, and rarely without ulceration. The signs of this condition are a harsh dry skin, small, soft, quick pulse, a parched tongue, of a bright colour, and smooth glazed appearance; frequent purging of slimy or watery evacuations; in some instances irritability of stomach, great emaciation, and an anxious expression of countenance. The patient rarely complains of pain, except on pressure over the abdomen, the integuments of which are hotter than the rest of the body, and retracted. In this condition it is not strength but stratagem which must effect the cure. The prognosis should always be guarded; for although many patients recover, even after ulceration has taken place, it is only by the utmost care. It is a grand principle here not to interfere too much with the operations of nature. Bleeding from the arm is certainly not advisable; nor, indeed, have I ever found it equal to leeches in reducing inflammation of the mucous membranes: a dozen or more leeches may be applied to the abdomen, and the bleeding encouraged by fomentations, until the pain be relieved, or the patient become faint. One, two, or three grains of calomel, may be given every or every other night, and two or three drachms of castor oil the following morning. These are almost the only medicines necessary: they act gently on the liver, and remove vitiated secretions from the alimentary canal. As to sudorifics in fever I have little to say, as I never saw any of much service except the warm bath. This tranquillizes the patient, and often produces sleep; and by bringing a flow of blood to the surface, relieves the intestines. Ablutions, with tepid vinegar and water, or the dilute nitro-muriatic acid, are particularly refreshing. The drink may be effervescing draughts, soda water, tea, or barley water, &c. &c. When the disease has been long protracted, and the patient very much reduced, it is advisable to administer mild unirritating

nutriment; broth, beef-tea, jellies, or the yolk of a lightly boiled egg, answer extremely well.

The danger of a patient labouring under continued fever is very much augmented by the peritoneal coat of the intestines becoming the seat of inflammation: it is frequently the cause of a fatal termination, and is a most difficult circumstance to treat: it is indicated by extreme tenderness of the abdomen, with distention of the integuments, irritability of the stomach, and anxiety in the expression of countenance: the bowels, which previously were probably relaxed, become obstinately constipated. Leeches, mercury, and blisters, are the means best calculated to give relief: the application must be prompt and decisive, as but little time can elapse before the patient is beyond the power of human skill.

[To be continued.]

TREATMENT OF PROLAPSUS ANI.

To the Editor of the Medical Gazette.

Sir,

Perhaps on an early occasion you will be good enough to insert in your journal the following communication: it contains the details of a mode of treatment of prolapsus ani, which, as far as I know, has not hitherto been employed by any one but myself.

There are three species of prolapsus occurring at the anus: the first may be produced by the invagination of the colon, of the cæcum, or of the small intestine; the second by the invagination of the rectum; and the third by the relaxation and projection of the mucous membrane of the rectum.

The first very rarely occurs, and against this art has not provided a remedy. Nature sometimes effects the separation *en masse* of the invaginated portion of the intestine, without producing any manifest injury to the patient.

The second species is very unfrequent in its occurrence, and the mode of treatment which has been adopted for its cure has been very generally unsuccessful; palliation alone being accomplished.

The third kind is a very frequent, and often a very distressing disorder; occurring principally in children and in old people. Many methods have been proposed and adopted for the cure of this disease. The great diversity which exists in the mode of treatment, even at the present moment, is, I think, the best possible evidence of the uncertain efficacy of each mode of treatment.

I trust that the employment of the remedy I am about to recommend will be found to prevent the recurrence of the two latter species of this disease; at least in the great majority of cases.

With regard to the mode of production of the first of these diseases, the information we possess is not sufficiently conclusive to warrant us in hazarding an opinion. The second of these diseases can scarcely occur unless there be relaxation of the levator and sphincter muscles of the anus.

In the third, it is only necessary that there should be relaxation of the mucous membrane of the rectum and of the sphincter of the anus.

Relaxation of the mucous membrane of the rectum is so frequent, the cellular tissue connecting it to the muscular coat is usually so lax, and often so infiltrated with serum, that we might, *à priori*, naturally anticipate a frequent occurrence of this disease.

To distinguish invagination of the colon or other intestine from that of the rectum, the process is usually simple; we merely take a common plaster urethral bougie; we pass it between the tumor and the anus: if it be arrested immediately (that is to say, within the distance of an inch or two from the orifice), we may fairly conclude that the disease is in the rectum; if it pass to the extent of some inches (by which I mean from five to six), we may as fairly conclude that the invagination implicates the colon or other intestine.

Yet this mode of investigation is subject to one fallacy; for a portion of the colon may pull down with it a part of the rectum, and in that case the bougie may be immediately arrested by a cul de sac: but here the quantity of intestine which has protruded cannot fail to set us right, if we should be in error. In well-marked cases we may sometimes determine at first sight whether the disease be an invagination of the colon or rectum; for if it be an affection of the former, instead of an irregular roundish tumor, making an inconsiderable projection, we find a cylindrical

flabby tumor, frequently many inches in length: but we must not always expect to see this wide distinction.

The second species is distinguished from the third by the bulk and resistant character of the tumor.

Having acquired this information, the next thing we have to attend to is the reduction of the tumor: how this may be best effected, has been so often and so fully described, that I shall not enlarge this paper by detailing the various means to which resort may be had.

When the reduction has been accomplished, the disposition by which the disease has been occasioned generally remains; so that this means of relief (which should never be considered more than palliative, and in some cases, it is true, as a preservative against fatal accidents) must never, under any circumstances, be regarded as a curative means.

I now come to the description of the means by which I always effect a radical cure of this disease. The reduction having been accomplished, the patient is placed upon a bed; the pelvis is then raised by pillows, so as to make the buttocks the most elevated portion of the trunk; the thighs and the folds of the nates are then so far removed from each other as to enable us with facility to make any application in the vicinity of the anus. A cautery, heated to whiteness, is now placed in the hands of the operator; who makes, according to the gravity of the case, one, two, three, or four applications of the cautery to the margin of the anus.

The exact point to which the application should be made is dependent upon the gravity of the disease: if it be not of long standing nor obstinate, the application should be made to the margin of the anus, but without implicating the mucous membrane; and the length of the eschar should be about half an inch: this should be the uniform length of the eschar.

If the case be an aggravated one, the application must be made, not only upon the epidermis, but also upon the mucous membrane.

It must be borne in mind that the object of the operation is to produce such an eschar as will be followed by suppuration; for in the process of cicatrization which follows suppuration, a fibrous tissue is generated, by which the anus will be so effectually contracted as to prevent the possibility of a recurrence of the disease; and it is upon the accomplishment of this effect that the cure almost entirely depends.

I have found in every case that the stimulus produced by the application of the cautery has occasioned the development in the submucous cellular tissue of an irritation capable of producing a firm and permanent adhesion of the mucous membrane.

In this operation, if the iron be properly heated, the pain is inconsiderable. And here it must be recollected that the application upon the living body of an iron heated to whiteness, occasions much less pain than the application of one merely heated to redness, and that the latter occasions much less pain than a grey heat.

No other dressing than a piece of dry lint is required, and this is retained between the folds of the nates, and removed only when the patient goes to stool: before it is replaced, the anus should be washed with warm water, by which any irritating matter will be removed. After the performance of the operation, the contractions of the sphincter, which have been excited by the application of the cautery, continue sometimes for three or four days.

If any pain be felt for a short time after the application of the cautery, fomentations of warm water will generally remove it.

I shall conclude this communication by detailing the particulars of two cases of this disease which occurred some months since: one in a spare man of sixty-two, the other in a child of three years. In the elder patient, in whom there was no hæmorrhoidal disease, the mucous membrane projected whenever he went to stool, and had done so during very many years. Occasionally difficulty was experienced in reducing it; and in consequence of this, on some occasions, it had remained unreduced for many days.

When I saw him, the prolapsus had existed for nearly four days; there was exhaled from it a fœtid sanious discharge, and it was considerably tumefied. The pain which the patient experienced was very severe whenever the tumor came in contact with his linen, or with any other body. Before I could succeed in reducing it, thirty-six leeches were applied, and a constant fomentation with warm water had been employ-

ed for some time. After its reduction, the patient was placed in the position I have already described, and the cautery was applied to the anterior and lateral parts of the anus, including about two lines of the mucous membrane. Some pain was experienced for three or four hours; it was relieved by constant fomentation with warm water. The patient did not go to stool for three days after the operation, and when he did, the membrane no longer protruded, neither has it done so to this day. The younger patient had suffered from prolapsus during five months; it occurred every time he went to stool. In this case only one cauterization was made, and that at the distance of a line and a half from the mucous membrane.

The following day, when the child went to stool, no prolapsus occurred, neither has it since. The cicatrization was completed on the twentieth day.

From the experience I have now had of this mode of treatment, I feel a perfect conviction that it will be found a valuable addition to our means of curing disease.—I am, sir,

Very faithfully,
BENJAMIN PHILLIPS.

17, Wimpole Street,

MEDICAL GAZETTE.

Saturday, December 22, 1832.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."
CICERO.

CLINICAL INSTRUCTION.

WHEN treating a short time since of the subject of the London schools, especially with reference to their capability of supplying a complete medical education, we touched but lightly on the department of clinical instruction—not because we had not much that was important to say about it, but because we did not deem it requisite at the time, while pointing out circumstances which appeared susceptible of improvement, to dwell upon this to the prejudice of other subjects which seemed to demand a more immediate degree of attention. In consequence, however, of some flippant and possibly mischievous remarks which have been made in another quarter, it may be as well to devote a short space to setting the matter in a correct point of view.

It will no doubt by many be thought superfluous to state that no city in Europe possesses a greater number of charitable endowments than London does, in the shape of institutions calculated for affording the amplest relief to the necessitous, and the most extensive opportunities of medical instruction:—that those opportunities are either neglected or lost, is the unfounded assertion which calls for our statement of the facts. There are seven large hospitals in the metropolis, attended by men of the first eminence in the profession, who are followed by hundreds of pupils: there is not one of these institutions in which clinical instruction is not given, and given in a manner which may challenge competition with any thing of the sort to be met with in the continental schools. The school of Paris (this we notice particularly, as it is held up to us by those whose convenience it is so to do, as perfection itself) has but three, or perhaps four hospitals, in which its professors teach; so that in comparing with the resources of our own institutions the extent and variety of practice which such establishments should afford, we have no reason to hide our diminished heads. In what, then, are we deficient? If it be said that the alleged superiority of Paris consists in the methods of teaching there adopted, we beg leave to ask what methods those may be that we have not got here? We say methods, for there is no invariable system of conveying clinical instruction in the French hospitals any more than in our own. Some of their teachers lecture at

the bed-side; some are more practical than didactic; some more didactic than practical; and some, in a studied manner, defer their remarks till they have their pupils collected in the theatre. There are varieties of the same description among ourselves. If M. Dupuytren teaches in one way, and M. Andral in another, so among us do Sir Charles Bell and Mr. Brodie prefer methods of clinique different from those of Dr. Latham or Dr. Bright. Various plans, in fact, are adopted in various schools: we have specimens of the foreign methods among us; and the French have the same; they are eclectics as well as we; there is no mode of clinical instruction peculiar to our Gallican neighbours. We have therefore still to seek in what the imagined superiority of the Parisian school consists? Possibly its advocates may tell us that in the school in question clinical instruction is imperative, while with us it is purely optional. This is a fact which we do not mean to deny; a provision, the propriety of which we do not mean to dispute; for if we did we should have to take into consideration the different systems, founded on different principles, pursued in each country. It is sufficiently known with respect to the medical establishments, as well as most of the other institutions of France, that they are all under the immediate management and jurisdiction of government; that every professor is an employé of the higher authorities; and that every pupil is recognized, and must be entered in the lists of the minister. What can be more directly contrasted with the free and unfettered mode of managing matters among us? There is no other country than this where so much is left to the discretion of the conductors of public instruction—where so much devolves on the uncontrolled agency and choice of those who are to be instructed—and where, we might add, there is so much so truly valuable effected by means that is perfectly free from compulsion. Here our schools are under no surveillance, except perhaps in so far as the new anatomy act has introduced that principle; nor are our teachers stipendiaries under the control of government officers. This is a distinguishing characteristic of our system, and one that has not been duly taken note of by the admirers of things foreign.

A journal, as notorious for its ignorance as for its total disregard of truth, would fain persuade its readers that pupils in Paris may attend medical lectures for nothing; that clinical instruction is given in the Parisian hospitals free of expense. It is most absurdly false. Clinical instruction, as well as every other branch of medical education, must be paid for in Paris as elsewhere. No student, unless he does it clandestinely, or by special favour, and without a chance of getting a certificate (for the professors are bound by an ordinance which renders this impossible), can attend clinical lectures at any of the recognized hospitals—the Hotel Dieu, La Charité, La Pitié, or the Hospice de la Faculté—without having paid his admission fees to the University—his *inscriptions*, as they are called; and when we come to calculate what these are, and compare them with other expenses of the French metropolis, so far from finding them *nothing*, we perceive that they are by no means so extremely moderate as some people might be induced to believe *.

Clinique, *chirurgicale*, and *medicale*, are, in fact, branches of the general course laid down for the French student: he has to pay for these as well as for all the other branches; and when he enters, having taken out his *inscrip-*

* The expense of these *inscriptions* exactly is,

For the first fifteen	- -	750 fr.
——the sixteenth	- -	35
		785 fr.

Or about 31*l* 8*s*. sterling.

tions, he may then choose whether he will hear Dupuytren and Chomel, at the Hôtel Dieu, or Roux and Bouillaud, at La Charité; and he receives his ticket of admission accordingly. Strangers, if they have not those tickets to produce, are liable to be excluded. Yet the triple bronzed journalist to whom we have alluded has the effrontery to say, that "the doors of the Hôtel Dieu are thrown open to strangers as well as to natives!" They are so, certainly, in one way; in the way which we have stated—*upon the payment of the necessary fees.*

So much, then, for the *gratuitous* system of lecturing in the French school. If a subterfuge be attempted, by asserting that the teacher receives nothing from the pupil in the Paris hospitals—or, to use the appropriate language of our contemporary, that he "disdains to extort money for delivering his discourses,"—we must only take leave to reply, that this is no more than what he ought to do: it would be "extortion," indeed, if he did, and would expose him to the loss of his appointment. The pupil must have already paid for those "discourses," or he has no right to hear them; and this being the case, it is mere humbug and vapouring to talk about "this generous, this noble treatment, of the *untaxed* inquirer" in the French hospitals. The truth is, that the French professors (though our silly neighbour seems to know nothing about it) are abundantly provided for: if they do not receive fees directly from their pupils, they do so from a fund which is altogether supported by those fees; they are, in fact, government officers, receive salaries as such, and have a direct interest in the number of students who perform their exercises in the French school for the attainment of their degrees.

One more piece of information for our veracious contemporary. He ventures to deny that clinical instruction is given in our hospitals: he knows he is telling a falsehood, for, with an amusing degree of absurdity, he has no sooner made such an assertion than he quarrels with our lecturers for the *quality* of the instructions which they give. With such an acute and impartial judge it would, as matter of course, be difficult to pass muster: just now, indeed, it would seem that nobody could do this except Dr. Elliotson or Baron Dupuytren. The surgeon of the Hôtel Dieu, for reasons not difficult to comprehend, is lauded as the *ne plus ultra* of lecturers; and at present the physician of St. Thomas's, alone of all his brethren in this country, enjoys the gracious patronage of the Editor of the Lancet. Now so far are we from wishing to decry either protegé of our contemporary, that we have already given the clinical lectures of his favourite physician, while we have no notion of discontinuing those of the surgeon: we only confine our selection to what we deem really good. *We* are not limited to the lectures of one teacher abroad and one at home: no ban of prohibition is placed upon *our* pages: we select from all, and are left free to commend what we approve, our worthy opponent being perforce obliged to commend the wares supplied by the very straightened sources which yet remain open to him. But we digress: our contemporary wishes it to be thought that clinical instruction is neglected in our hospitals: it is merely an interested and a foolish wish to mislead his readers. There is no hospital in London that receives pupils in which clinical instruction, and that of a superior description, is not given. Need we do more than refer to the clinical lectures of this journal?—to those of Latham, and Elliotson, and Thomson, and Watson, on medicine,—or to those of Bell and Brodie, and Key and Earle, on surgery. But why particularize, when no student can go to any hospital in London, (may we not

add, the provincial towns?) anxious to receive clinical instruction, without the means of obtaining it? And again, our consistent antagonist assumes either that there is, or that there is not, any such thing as clinical instruction, just as suits the argument of the moment. At present we are told, for reasons above hinted at, that there is only one clinical lecturer in London, and one in Paris; but very lately it was his cue to assert the direct contrary, and then we were told that clinical lectures were at last given because *he* had so ordered it. The attempt to cushion the fact of the system of *clinique* pursued in the establishments of the metropolis, is rather too gross: yet it is not a little amusing to think how it may go down with the readers of the periodical in question. With regard to the insinuation (rather loudly expressed), that we have nothing in this country to compare with Dupuytren—we conceive it to be altogether a matter of opinion; and one in which others, under favour be it spoken, are as competent to decide as our would-be Aristarchus.

ANOMALOUS INQUEST BEFORE A CORONER.

Some of the Evening Papers, this week, contained a very extraordinary report of an inquest (?), held by Mr. Stirling, the Coroner, to inquire into the nature of the death of young Grimaldi, the well-known clown. A jury was summoned—witnesses were examined at some length—and both coroner and jury expressed themselves satisfied; while all the time *the body was not seen*, having been interred a day or two before in the church-yard. Among the witnesses was a medical man, named Langley, who had attended the deceased; but he had not opened the body, nor could he give any consistent account of the violent symptoms with which his patient was carried off, although he ventured to assert that they were *not* owing to the severe bruises which had been inflicted on the body of the deceased. Both law and physic seem to have been sadly confounded in this business. An inquest is held without a view of the corpse; no verdict (of course) is returned; and further inquiry is deemed unnecessary, in consequence of Mr. Langley's evidence. We do not enter into the particulars, as they have already been given the public; but we confess we think the matter by no means satisfactorily settled. It is still a question whether Grimaldi died a natural death: and should further investigation be deemed requisite, we do not see how the medical witness can escape heavy censure, who, by omitting to perform the requisite autopsy, not only neglected the possible advancement of science, but materially contributed to defeat the ends of justice.

DEATH OF MR. JOBERNS.

Mr. Joberns, senior-surgeon of Middlesex Hospital, died a few days ago rather suddenly at Woodstock, where he had gone on a visit. Mr. Joberns was an intelligent and worthy man, and belonged to a race of surgeons who are rapidly passing away—the remnants of a by-gone generation. Mr. Arnott, the present assistant-surgeon, as a matter of course, will be his successor. Mr. Shaw, Mr. Tuson, and Mr. Phillips, are in the field as candidates for the expected vacancy in the assistant-surgeoncy.

DEATH OF RUDOLPHI.

M. Rudolphi, the celebrated Prussian physician, well known by his contributions to physiology and natural history, died at Berlin on the 29th ultimo, in the 63d year of his age.

MEDICO-CHIRURGICAL SOCIETY.

Tuesday, Nov. 27, 1832.

Mr. Lawrence in the Chair.

Mr. Lloyd on Fatty Evacuations from the Bowels.

A gentleman, aged 47, after eating heartily of cray-fish, was seized with violent pain in the epigastric region, but especially in the situation of the duodenum. This was succeeded by a sharp attack of urticaria, with hepatitis, and subsequently of jaundice. When the jaundice was fully established, the hepatitis subsided, and the patient regained a comparatively good state of health and spirits. Pressure on the situation of the duodenum, however, always gave pain. For many months the patient remained in this state, deeply jaundiced; the urine, saliva, tears, mucus of the nose, and serum of the blood,

were all loaded with bile, and yet not a particle passed through the duct into the intestine, the motions being as white as pipe-clay. All the time the appetite was good, no inconvenience was experienced from taking food, and the bowels acted freely and most regularly. At length a renewal of the hepatitis occurred, which was followed by a discharge of *fatty matter* from the bowels. It appeared like melted fat; and when cool, was about the consistence of butter. It swam in water, melted at a moderate heat, and was highly inflammable. Sometimes portions of it would be mixed with the fæces, but generally the two matters were distinct. Its colour was sometimes darker, sometimes lighter, but always yellow. Contemporary with the appearance of the fatty matter, the alvine evacuations became of a darker colour, but never assumed that of fæces, coloured with healthy bile. And it was, moreover, observed, that whenever the fatty matter ceased to pass, the motions grew pale, as at first; but they always resumed their darker colour as the fatty matter reappeared. In the last week of the patient's life, there was none of the fatty matter perceived; and during the whole of that time the motions put on their white pipe-clay colour.

There was another new symptom occurred at the time, or soon after, that the fatty matter made its appearance. Hitherto there had been a total freedom from sickness; now, on the contrary, scarcely a day elapsed without the contents of the stomach being thrown up: it occurred almost without effort, as in a case of simple stricture of the pylorus. There was no nausea, the appetite was good, and directly after vomiting there was the utmost eagerness to take food; and such may be said to have been the case till the day of the patient's death. The bowels acted regularly to the last. The patient's death occurred between ten and eleven months after the attack.

Sectio Cadaveris.—The whole of the external and internal parts of the body, as far as were examined, were of a deep yellow colour. The stomach was of immense size, extending across the abdomen from ilium to ilium, and its greater curvature almost reached the pelvis. In its cavity there were from three to four pints of dark fluid, smelling of wine, beer, &c.; its coats were thickened, and its inner membrane was more vascular than natural. Immediately beneath the pylorus a hard mass was discovered, which proved to be principally made up of a portion of the duodenum, the head of the pancreas, some absorbent glands, and condensed cellular substance. The duodenum, towards its middle, was so much contracted, that its cavity was in great measure obliterated; so much so, that the larger end of a common blow-pipe would hardly pass through it. In no other part of the alimentary canal was any disease discovered. The pancreas was healthy, but its duct was enlarged. The liver in its structure shewed no diseased change, except such as is seen in the simplest form of chronic inflammation. It appeared more bulky than common, as throughout its substance the pori biliarii were enormously distended, as were the hepatic and common ducts, and also the gall-bladder. The orifice of the common duct in the duodenum was completely closed. In no other part was any disease observed. There was not the slightest indication of malignant disease. The morbid parts were exhibited after the reading of the paper.

December 11, 1832.

MR. LAWRENCE IN THE CHAIR.

A PAPER by Mr. Cæsar Hawkins was read,

On Sloughing Abscess connected with the Liver; with Remarks on Encysted Tumors of that Organ.

The first case on which Mr. Hawkins's observations were founded, was that of a man, aged 31, a patient in St. George's: he had lived intemperately, had been in the East Indies, and suffered from liver complaint. He came into the hospital in consequence of a swelling in the right hypochondrium, for which he had been bled and salivated without effect. It was an oblong swelling, extending across the abdomen above the umbelicus. It appeared to be connected with the liver, and fluctuated obscurely; it was opened by Mr. H. Five or six ounces of thickish dark-green fluid were evacuated, which, upon the addition of nitric acid, seemed to indicate the presence of biliary matter. The patient was relieved by the discharge, which was kept up for some time: it at last, however, began to appear mixed with arterial blood, and the apertures began to slough. A large sloughing sore, four inches by two and a half, now nearly covered the place of the original tumor; it was attended with hæmorrhage, and a peculiarly offensive discharge wholly unmixed with pus. In spite of every remedy, local and constitutional, the man died five months after the abscess was first opened. On examination after death, it was found that, of the abdominal parietes, nothing remained but the peritoneum, which adhered to that of the liver. Strange to say, there appeared to be no marked disease of the liver; there were no remains of a cavity; nothing to indicate the existence of any local affection of the organ, except a very slight thickening of the peritoneum, with a whitish mark resembling a cicatrix.

A female, aged 22, died of a similar complaint in the same hospital, and the symptoms were as like as possible. She sunk under the sloughing process, which continued for about four months. The liver was remarkably healthy; but close to the peritoneal covering of its surface there was observable a yellowish-white mass, about the size of a small nut, with slight condensation of the liver around it to the extent of an inch.

Mr. Hawkins does not consider these to have been cases of abscess of the liver, for reasons which he stated at length. But his impression is, that the disease originated in one of those encysted tumors which not unfrequently form on the surface or at the margin of the liver, below the peritoneal coat, and may be termed aqueous encysted tumors. He treated fully concerning the nature of these structures, and their relation to hydatid cysts and other analogous formations. Mr. Brodie (he went on to relate) had a case like the preceding under his care some years ago, in St. George's Hospital. It was that of a boy of 12. Here, by the introduction of a trocar, a pint and a half of clear watery fluid was drawn off; pressure by bandaging was applied; the cyst was apparently obliterated; and the boy left the hospital cured. Mr. Brodie has given an account of another similar case in the Medical Gazette (vol. i. p. 334): it was the case of a young lady of 20. Three pints of fluid were drawn off, and the treatment generally was quite successful. Mr. Hawkins considers these as examples of the success which may be anticipated when the complaint is treated early: though even after inflammation has set in, and the nature of the contained fluid has been altered, the same result may be expected. In proof of this, he referred to a case treated by Dr. Thomson, and an account of which is in the Gazette, vol. i. p. 168. Urgent symptoms are frequently produced by the growth of these tumors, in consequence of their encroachment upon the thorax compressing the lungs, and those symptoms may be mistaken for hydrothorax or hepatization, or actual effusion into the pleura may ensue. He referred to a case in the Hist. de l'Acad. des Sciences (1732), for an example of this latter description. A soldier, after complaining for two years of very great dyspnœa, died; and there was found a cyst of the liver containing yellowish-green fluid. There were also cysts of the lungs. In another volume of the Acad. des Sciences, there is an account of a girl of 8, who had a tumor in the situation of the liver. Owing to a violent accident it disappeared; but inflammatory symptoms followed, and the child died. A rupture was found, to the extent of three or four inches, in the right lobe of the liver, in which was found a cavity lined by a cyst.

Other cases in point were adduced by Mr. Hawkins, from journals, foreign and domestic. With regard to the occurrence of hæmorrhage from the cavity of the cyst, and the fungous ulceration, observed in the two cases mentioned in the beginning of the paper, both have been noticed before, when similar tumors have formed in other parts of the body. A female patient of Mr. Brodie's had a tumor in the neck, apparently connected with the thyroid gland, which was punctured: a small quantity of fluid was discharged, but the cyst filled with blood, and, when re-opened, hæmorrhage took place. Mr. Brodie dissected out the cyst; but sloughing ensued, and the woman died. When the breast is affected in like manner, a similar result may happen. In one case of this sort the breast had to be removed, and the patient became quite well. Mr. Hawkins does not think, after all, that the fungous growth is of a malignant character; or that, as in fungus hæmatodes, from its occurrence in one part we should be led to apprehend its occurrence in another.

In conclusion, Mr. Hawkins promised to take an opportunity, in a second part of this paper, to point out briefly the circumstances which attend hydatids in the liver, and the discriminative characters of both them and the aqueous tumors of which he now treated.

CLINICAL LECTURE
ON
DISEASES OF THE URETHRA AND NECK OF THE BLADDER.

Delivered at Middlesex Hospital, Dec. 15, 1832,

By Sir Charles Bell.

Gentlemen,—To-day I shall beg your attention to the diseases of the urethra and the neck of the bladder, and particularly to the operations performed upon those parts. I am almost afraid to ask you if you have attended to the cases which I am about to enumerate. You will see that a commentary on the cases of these patients does, in fact, embrace the whole of this important branch of the art of surgery. The *first* case on the list is that of a distended bladder, with paralysis of the lower extremities, from injury of the spine. The *second* case is of distended bladder, with a false passage made by the catheter,

and a stricture. The *third* case is fistula in perineo, consequent upon the operation of piercing the stricture from within. The *fourth* case is stricture of the urethra, with prolapsus ani as a consequence: in this case, too, the operation of piercing the stricture had been performed. The *fifth* is a case of a very narrow stricture, causing retention of urine. The *sixth* is ulcerated urethra and fistula in perineo; not from stricture, but a direct consequence of gonorrhœa. The *seventh* is fistula in ano, attended with rupture, or rather ulceration of the urethra, in which flatus is occasionally discharged from the penis. The *eighth* is extravasation of urine from stricture of the urethra, combined with fistula in ano. In the *ninth*, the patient suffered injury of the perineum from the pummel of a saddle, which gave rise to a fistula in perineo: he is now an out-patient.

I am confident that you feel the whole subject to be before you, and you see at once the importance and the difficulty of it. There is not one of these patients who has not been in danger of his life—there is not one who has not still to suffer a great deal, either by the inevitable progress of the disease or by the operation necessary to his cure.

You have reason to be convinced that the opinion was a false one which supposed that these diseases of the urethra were almost peculiar to the rich. It arose from the diseases of the rich being at ended to, while those of the poor were neglected. When I first came to London, I had read all the books on stricture, and I had endeavoured to see the appearances in the dead body; but I found the knowledge of important facts confined to a very few, and the correct descriptions of the state of the parts only in Mr. Hunter's works. I set about investigation, and I collected, and dissected, and prepared 105 specimens of stricture in the urethra; not, of course, from the higher class of patients, but from men in hospitals and from poor-houses. You see, from the enumeration of the cases to-day, how the matter is—that the very lowest classes of society are as subject to this disease as the luxurious and rich. These local disease are not consequent (as once was the opinion) upon constitutional disease, as gout; but by far the greater number of them are to be referred to inflammations at an early period of life;—and the disease of the bladder is for the most part consequent on that of the urethra.

I will now call your attention to the first case.

1.—*Case of Distended Bladder, with Paralysis of the Lower Extremities.*

Wm. Arnol, æt. 21.—This man was brought some distance from the country, and admitted October 30th. He had partial paralysis of the lower extremities; his urine dribbled from him continually, and he was provided, by the surgeon who formerly attended him, with an urinal, which was fastened round his loins and received the water as it flowed. His fæces also passed involuntarily. He stated, that, a month before, he was employed in cutting wood; and whilst standing upon the branch of a tree, he slipped and fell to the ground, a height of twenty feet. He lighted upon his feet, and then fell flat upon his back. He was not stunned, but found, upon attempting to rise, that he had lost the power of his legs, and his skin was quite numb. He experienced no pain in his back; and when the surgeon examined the spine, under the impression that there was fracture, no marks of injury were apparent. After two days had passed, a catheter was attempted to be introduced to draw off the urine, which had not flowed since the accident; but the surgeon failed, and the water, from that time, has been allowed to dribble from him involuntarily, as it does at present. A fortnight after the accident, he began to feel pain in the region of the bladder, for which leeches were applied. At this time he was attacked with scarlet fever, and the skin is now desquamating. He also, about the same period, began to recover, in some degree, the command over his legs. He can draw them up in bed towards his abdomen, but they are still very weak; the skin, although not altogether deprived of sensation, possesses it only in an imperfect degree. He can sit up in bed, without experiencing any pain in his back. The spine has a lateral curvature in the lumbar region, the curve of which is only trifling: there is also a prominence of the vertebræ at the same part; but he complains of no pain, however roughly they are pressed or kneaded with the hand.

The first thing which was attended to upon his admission into the hospital, was the condition of his urinary bladder. Upon examining it, it was found to be enormously distended; the fundus being above the umbilicus, and requiring the fingers to be spread widely over it to embrace it fully. When the catheter was introduced, a large chamber-pot was nearly filled, to the patient's great amazement, who did not suffer pain from the distention, and did not conceive that his bladder held any urine.

Since his admission, up to the present date, the urine has been drawn off regularly twice a-day by the silver catheter. For a week past he has succeeded in making water once a day without the instrument. He has now the command over the action of his bowels. He has been able,

with the assistance of crutches, to walk from his bed to the fire-place, where he sits most of the day, and without experiencing pain in his back. He informs us for the first time, that, when he was ten years of age, one of the wheels of an unloaded cart passed over his loins, while he was lying upon his face in a hay-field; but he received no material injury, as he was able to get up immediately after the accident, and even to run to his home. This, he says, may perhaps account for the appearance which is observed in his back.

Gentlemen,—In reflecting on this case, the first consideration is, whether the man's condition be the effect of the accident or of disease?—for you ought to be aware that his condition is like a disease that presents itself to us very frequently. I have been six times in consultation, within a short period, on affections similar to this, with Dr. Maton, Mr. Brodie, Mr. Guthrie, Dr. Young, and other most intelligent practitioners. There is still a question whether the debility is caused by an affection of the spinal marrow or of the brain. These patients labour under the following symptoms: paralysis of the lower extremities, not complete, but with diminished sensibility, a certain unsteadiness in walking; and fullness and softness of the belly; a tightness across the stomach; a difficulty of making urine, amounting sometimes to total obstruction, and an inability to retain the fæces. Now these symptoms, which are frequently presented in practice, are so precisely those which you find in this patient, that I cannot altogether remove from my mind the idea that this may be one of those cases of paralysis of the lower part of the body. Is it a case of disturbance of the spinal marrow, arising purely from the accident, or is it a case of disease of the spinal marrow?

There is something in the case to which you must attach importance, and it is the circumstance that is last narrated. I allude to the curvature in the spine: for although it is stated that this is a *lateral* curvature, yet you must have seen that, when I asked the patient to sit up in bed, just about the part where the dorsal vertebræ join the upper lumbar vertebræ, there is a remarkable projection; and, on further examining the part, you find there is an unusual immobility of the spine there. You know very well that this is naturally the most pliable part of the spine; but in this man it is quite the reverse. Observing this, and inquiring into it, the patient recollects himself, and states that a waggon went over his back in childhood. When you consider how scrofulous action is apt to take possession of these bones, and how readily this diseased action is to be excited by any such injury as this at an early period of life, you will, I think, agree with me that there has been an injury to the spine, followed with a certain curvature and a union of the bones of the vertebræ, by exostosis of their bodies.

Now if that be the condition of the part, what is the natural reflection upon it? I can tell you what happens in similar instances—viz. that when a man, a little farther advanced in life, has had his spine thus consolidated, and has afterwards fallen, the fracture has taken place in that part of the spine which is strongest. At least you would be apt to say that the strongest part of the spine was that where the bodies of the vertebræ are joined by bone: but it is really not so; because nature has made the strength of the spine to consist in its elasticity, not in its inert resistance; so that when the rest of the spine is elastic, and a certain portion is united by bone, it is there that the force is concentrated, and the injury done. In this hospital we have found repeated instances of the spine fractured across at the ossified part; and I can the easier conceive that this man has suffered a higher degree of concussion in falling from the tree, and that the spinal marrow has suffered concussion where the spine itself is most firm.

Well, notwithstanding all this, the circumstance of the accident, the narrative of the symptoms, the man's appearance altogether, constitutes a case so distinct, that you are obliged to enter upon a certain line of practice, for the purpose of diminishing inflammatory action in the membranes of the spinal marrow.

I will not touch farther upon the subject than to beg your attention to the introduction of the catheter in this and similar cases. Let us suppose that the case is one of injury of the spinal marrow, and that paralysis is the consequence: how is it that there is distention of the bladder without obstruction? There is no stricture nor obstruction: why is it, then, that the bladder is distended? This is an important consideration: it is, indeed, a leading subject, on which depends the comprehension of the whole detail. Most of you, I have no doubt, have attended a little to midwifery; and I must recal to your notice, that when the child's head is detained in the pelvis, and the labour is protracted, it will often happen that on the day subsequent to the labour there is an immense tumor in the abdomen, and that tumor is the distended bladder. Why should a temporary obstruction of the functions of the bladder be attended with retention of the urine to that degree that the bladder has been known to ulcerate and burst? You must recollect that when the urinary blad-

der is distended beyond a certain degree, it becomes paralyzed, the *detursor urinæ* becomes incapable of acting, and the bladder is so distended at length that the pressure of the diaphragm, and of the abdominal muscles, come to be the only agents in expelling the urine. Whatever may be the cause of the distention, you see this effect, that the person cannot evacuate the urine; and this man comes up from the country, and into the hospital, conceiving, as the patient almost always does, that his bladder cannot retain so much as a cupful of urine; and, accordingly, the case narrates that he was astonished when, upon introducing the catheter, a chamber-pot full of water was drawn off. He could not conceive it possible, for he believed that the last drop of urine was discharged, because he had to strain with the muscles of volition to accomplish what he did.

Presuming that the accident is the sole cause, we reason thus. There has been a disturbance of the natural sympathy that exists betwixt the muscular coat of the bladder and the muscles at the neck of the bladder, and the consequence of that derangement has been a great distention of the bladder, and after that distention has taken place there has been an inability of the bladder to evacuate its contents. Well, then, it is necessary to pass the catheter; and all I have to say upon that head is, that you must be especially careful in passing the catheter in these cases—that you must pass it slowly, gently, with every possible attention and precaution, and avoid any thing like that dexterity which by French authors is called *tour de maitre*. It is especially necessary that you should be cautious in these cases, because there is no sensibility of the part. In passing a catheter in a man who has the natural sensibility of the part, he cries out, he shrinks from you, he will hardly permit you to do harm, or to turn the instrument in a different way from what is right. You are then, by the sensibility of the part, made aware when you are doing wrong; but when a man has an injury of the spine which obliges you to pass the catheter, you have no sensibility to assist in the direction of the instrument, and you may twist the instrument, and thereby make an abrasion of the membrane, or so injure the urethra as to lay the foundation for a false passage.

Now it will be found that when a false passage is made, or there has been a rupture of the urethra, (and the next case will prove it sufficiently) and the point of the catheter has gone out of the urethra, there is the greatest probability in introducing it again that you hit upon the false passage, the edge of the ruptured part being so apt to catch the point of the catheter, and direct it out of the urethra.

An opinion has arisen that the amoniacal condition of the urine in these cases proceeds from an imperfect nervous power influencing the kidney, and that when the spine is hurt, and there is consequently paralysis, that there is a changed condition in the secretion of urine, and hence the amoniacal urine. I have not made my mind up about it, but I certainly see this state of urine when there is no reason to conclude that the nerves of the kidney are injured; and I am inclined to believe, that what with the urine retained in the bladder, together with the necessity for frequently introducing the catheter, and the almost necessary consequence—inflammation of the bladder, the ammoniacal urine is produced; and here is an additional reason for your introducing the catheter with great care in these cases of paralysis; for if you make a hitch, and bring blood, and cause inflammation of the bladder, you find offensive and stimulating urine to follow, which increases the fever.

To bring us again to the practical point, that we may not wander into speculation, I will ask my young friend here to read the next case.

2.—Case of Distended Bladder, with Stricture and False Passage.

Henry Hautboy, æt. 22, a waiter in an hotel, was admitted on Tuesday evening, December 4th, suffering from retention of urine. It appears that this man has had a stricture of the urethra for several years; that he has been subject to occasional total obstruction; that on these attacks he has had recourse to a surgeon, who has relieved him by an instrument; that on this last occasion the operation failed, and nothing but blood came. He states that his urine always flowed in a small stream. Attempts have been made to introduce the catheter since he was admitted into the hospital, without success. The usual means of relieving the spasm of the neck of the bladder have been employed, but now the bladder has risen above the pubes, and he is in great suffering.

The surgeon of the week introduced a silver catheter, of a small size; and putting his finger in ano, said that he felt the instrument running close to the coats of the rectum in a false passage, and that it must have gone out of the urethra just under the arch of the pubes; then keeping the catheter in its place, he begged his colleagues to examine if it were not so. Upon this, the other surgeon, withdrawing the instrument altogether, again introduced it, and with ease and dexterity passed it into the bladder. The water being drawn off, the catheter was retained in the urethra, and fixed with the proper bandages. In the evening the instrument slipped out of the passage, upon which the house-surgeon introduced it again, and the water flowed,

although he was of opinion that he had not passed the catheter fully into the bladder. As it was found after this that the patient could evacuate his bladder without difficulty, no further attempts were made to introduce it. Since that time he has been free from suffering, and can retain his urine for the natural time.

Now, GENTLEMEN, I will bring your mind to reflect on this subject by stating to you that when a house-surgeon is about to be introduced here, he undergoes an examination on certain important practical points, and he is asked, what is to be done when a patient is brought into the hospital with retention of urine? He is then asked what he understands by the terms suppression and retention of urine? What is the condition of the patient when he has introduced an instrument into the bladder, and no urine flows? He is then asked, what is to be done when a patient cannot make urine, the bladder containing urine? It is not expected that he will say, "I would introduce a catheter," because there come men into this hospital in whom it would be most dangerous at once and inconsiderately to introduce a catheter. It is expected that he should distinguish the cases, consider attentively all the features of each individual case before he thinks of the catheter; and, of course, the same will be expected of you in practice. If a person come into the house, or you be called to a person with a narrow stricture, and with a distended bladder, and you at once have recourse to the catheter, and it may be, boldly attempt the introduction of it, you complicate the case exceedingly. What is to be done then? Why this: you are to make a careful inquiry into the condition of the patient. If he be an old person, you are to think of disease of the prostate, and your questions are to be made with a view to that. If he be a young man, you are to consider whether he may not have gonorrhœa; whether he may not have inflammation of the neck of the bladder; whether he may not from modesty have retained his urine too long; because if a young man have been a situation where he could not make water, and if in that state the urine has accumulated so as to distend the bladder greatly, then you return to the point which I have explained—the bladder has been over-distended; and when he was released from the restraint of company, and thought to pass his water, he could not make a drop.

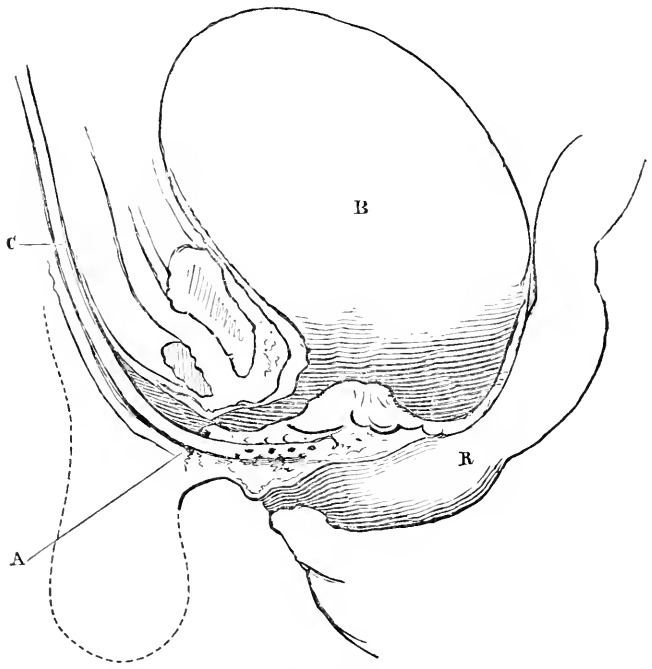
In such a case, where it is quite clear that there is no obstruction in the urethra, the temptation to use the catheter is very great, and thus at once to relieve him. But where the narrative leads you to suspect that the patient has a narrow stricture, and that it is a spasm consequent on the inflammation attending the stricture which has brought him into this condition, you must have him bled; and having been bled you must put him in a warm bath, and give him a large opiate, when you will have the pleasure of seeing the urine flow. By bleeding, by leeching, by fomentation, by the warm bath, by a large dose of opium or Dover's powders, you find that the sensibility of the inflamed part is diminished, that the spasm is removed, that the power of freely evacuating the bladder is restored, and you do infinitely more for the safety of that man than if you passed a catheter, and burst through the stricture.

But it appears that in the case before us the obstruction did not arise from a narrow stricture, and we are left a little in the dark even now as to the cause of the obstruction. We found that he was subject to this obstruction; we heard him state that he made a small stream of urine—this looks like a stricture; we found that he went to his surgeon, and had a small catheter introduced, to relieve him occasionally; and we found that on the last occasion the instrument was used, but without entering the bladder; and instead of urine, blood appeared. What does that imply? It implies that the urethra is torn; it implies that the catheter, instead of passing freely with a sweep into the bladder, has passed out at the lower part of the urethra, at the posterior part of what is called the sinus of the urethra, and which in this instance is directly anterior to the ligament which binds up the urethra to the pubes.

[The learned lecturer here handed round a sketch which he had made illustrative of the exact position at which the instrument had perforated the urethra, a copy of which will be found in the next page.]

Now when I came to pass the catheter, as has been stated, it passed to the place which was, as it were, made for it, where the urethra had been ruptured. There is a sensation produced, not easily conveyed in words, when the catheter passes out of the urethra. There is a sort of roughness, yet no obstruction, because the false passage is free, but a certain roughness which will lead the surgeon to say, this instrument cannot be in the smooth mucous surface of the urethra. When I found this, I looked to the direction of the instrument, and it did not appear to me exactly to correspond with the rapha, and therefore you saw me oil my finger, and introduce it into the rectum. On its introduction, I was convinced that my first idea was right, that the instrument was not in the canal, and that it passed close to the membrane of the rectum. I did not feel the usual thickness of substance between the finger and the catheter, and such as there would have been had the instrument been within the prostate,

or even within the membranous part of the urethra, and I therefore said to my colleagues, "I do not think it is in the urethra; I wish you would feel and ascertain



A—the point at which the catheter has passed through the membrane of the urethra.
B—the bladder. C—the catheter. R—the rectum.

this: *I think it has passed out just under the arch of the pubes.*" Instead of my colleague feeling this, he withdrew the catheter, and giving it another direction, he with great dexterity introduced it at once into the bladder, and very happily for the patient.

Here we have a subject on which I am very anxious that you should give me the most diligent attention. Suppose the bladder were distended, and were rising up to the umbilicus; (this man's bladder was as high; I could feel it bulging upon the rectum; and on striking the belly, there was an undulation against the finger) suppose such a case occurring, and that you did not succeed with the catheter, what is the next thing to be done? This brings us to the question of puncturing the bladder; and I am very desirous that on this question you give me your undivided attention, because I have found a letter from Sir Astley Cooper, and also from my friend Mr. Travers, touching this very subject. There are in the old practice of surgery three ways of puncturing the bladder—one above the pubes, another by the rectum, and a third by the perineum. Do not confound the old operation, which you find described in the Transactions of the Academy of Surgery of Paris, of thrusting a trocar by the perineum into the bladder with the operation which is performed by us here in London, and which consists in opening the urethra behind the stricture, and betwixt the stricture and the bladder, and not in thrusting the instrument into the bladder by the side of the prostate.

It appears in two different publications —of course without any connexion with me at all—that I have been the inventor of this operation; to which Sir Astley Cooper very naturally says, "no, I performed this long ago;" and he refers to our mutual friend Mr. Travers. I am happy in having both these gentlemen for my private friends; and in a professional view it becomes a duty to respect and to see justice done to him who has so long been the head of his profession. Mr. Travers writes that he has seen Sir Astley Cooper long since and often perform this operation of opening the urethra behind the stricture, to relieve the

distended bladder, instead of puncturing it. The important point for you to observe, independent altogether of the question who did this operation first, is that you have the highest authority in the profession for doing it. That is the single and important question for your consideration; and as to myself, I beg you will distinctly understand that I at once resign all pretensions to have been the first to perform this operation. Such a thought never entered into my head; and my friend Mr. Philips, the author of the book which has given rise to this correspondence, has probably misunderstood the question. I think it has arisen out of this circumstance, that younger men than me have assumed to themselves that they have been the first to operate in this manner; and he, perhaps, in vindication of his own teacher, has said, "no, Sir Charles Bell has advocated this practice long ago." I fancy it has occurred in this way.

Now mark me; here comes a most important question. I have performed, and I have recommended, the operation of cutting into the urethra behind the stricture, in another case altogether, not in the case of a distended bladder. The affection in which I conceive it most important to have recourse to this, is a totally different condition of the patient. I venture to say that for one man who dies with a distended bladder, a hundred die of the complaint to which I shall now allude.

The case is this:—A man has a very narrow stricture; the surgeon cannot pass an instrument through the strictnre; he has exhausted all his means of alleviating the spasm attendant upon the stricture; the patient is night and day distressed with ineffectual efforts to make water; he makes very little at a time, and even then there is severe straining; every twenty minutes he is up in bed, and on his knees, endeavouring to press out the last drops of water; the bladder is contracted, so that its cavity is not larger than that of a walnut-shell. It is not a case of distended bladder, for the moment the urine comes down through the ureter into the bladder, that instant there is micturition—a call to expel it. In this condition a man will pass one or two days; he will then be seized with fever—he will very often become delirious—he will even have all the characters of a maniacal person, or effusion will take place into the brain, and he will be in a comatose state, and so he will die; and when you examine by dissection, you will find the bladder contracted in the manner that the old pathologists (if pathologists they could be called) would designate by the term schirrosity of the bladder. It is thickened, it has a small cavity; the peritoneum over it is inflamed; the internal surface is gorged with blood, and black, and the ureters and pelvis of the kidney are distended and inflamed.

Here are the facts, and I conceive that it is of the very utmost consequence to determine what should be done. When you find a man thus straining and continually emptying a bladder that is not dilated, you cannot puncture it from above, it is so small; you cannot hit it through the rectum, it is so small; it has no cavity into which you can thrust an instrument But if you divide the urethra—and I advise you to do it just behind the stricture—the most extraordinary phenomena take place. You would naturally suppose, and you will be borne out in supposing, according to the principles of mechanism and hydrostatics, that in proportion to the obstruction in the urethra would be the action of the bladder: but it is quite the reverse. A narrow stricture is attended with a contracted bladder; and the oddest thing of all (and which is only to be explained by a reference to the vital principle of the part, and not to a mechanical principle) is this—that no sooner does the urethra become free, than the patient, after passing a very little urine, has a longer interval of ease, and, instead of rising twenty times in the night, he perhaps rises only six; the day comes, and he rises only every hour, and gradually the bladder, being no longer resisted, is observed to dilate more and more freely, until at length it allows the accumulation of the natural quantity of urine, and of course the water comes only at the natural period.

Now this is the consequence of dividing the stricture in the perinæum; and so far from having my vanity hurt, I should be delighted if Sir Astley Cooper would say that this is a case also in which he has divided the urethra, because, if he can say so, see what an important acquisition we have. Then your minds would be relieved at once; because, having his authority, I have no hesitation in saying that you have the highest authority in the profession for dividing the urethra in the perinæum, relieving the bladder, and restoring the patient from a state of extreme danger to life.

It was my intention to have had another case read, but the time has elapsed. This subject is an important matter of practice—important to you in after-life, and therefore I must beg of you to give me your attention on Saturday next, in order that we may go fully into it. You see how I am impressed with its importance; and I do assure you that it is in consequence of the frequent loss of life which I have seen, resulting more from wrong principles than awkwardness or want of dexterity on the part of the surgeon.

WESTMINSTER HOSPITAL.

Case of Pneumo-Thorax, in which Paracentesis was performed, with an Abstract of a Clinical Lecture,*

By G. Hamilton Roe, M.D.

Wm. Laird, æt. 25, by occupation a groom, was admitted into the hospital, August 27th, labouring under the following symptoms. Severe pain across the chest, with violent cough, and some expectoration; hoarseness, and night sweats. He stated, that, till July last, he had always enjoyed good health; that then, after exposure to cold, he was seized with pain in his chest, cough, and expectoration; which were relieved by two bleedings. A second exposure, shortly after convalescence, brought on his present symptoms.

Percussion elicited a rather duller sound than natural over the whole chest, particularly on the left side. Respiration pure, but feeble at both sides. No resonance of the voice.

Till the 15th of September he exhibited signs of amendment under treatment; on that day he was seized with a severe stitch under the left breast, much increased by inspiration; attended with hot skin and rapid pulse. Local bleeding relieved these pleuritic symptoms, but his cough, hoarseness, and *mucous* expectoration, continued.

On the 7th of October he was suddenly seized with dyspnœa, soreness of the chest, inability to lie on either side, increase of cough and expectoration (muco-purulent). Respiration laborious (number 38). He could not inspire fully. Voice almost none. Pulse 120; face flushed; skin very hot and dry; considerable night sweats.

On the 13th the left side of the thorax appeared more prominent than the right; the intercostal spaces were enlarged, and there appeared but little motion in it during inspiration. Percussion elicits a tympanitic sound all over this side, except in the axilla, where it is less clear. Respiration absent at this side, except immediately under the clavicle. When the patient sits up, the sound on percussion becomes dull, anteriorly and inferiorly, at the left side. *Tintement metallique* distinctly audible at the inferior angle of the scapula; *ægophony* distinctly audible at the same place.

At the right side the sound on percussion is rather dull; the respiration is puerile; there is considerable resonance of the voice under the clavicle. The heart pulsates at the right side. (Diagnosis: hydro-pneumothorax of the left side, with most probably a fistulous opening in the lung. Right lung healthy, except at its apex, where tubercles doubtless exist.)

* It should be stated that the lecture was given before the patient was operated on.

The patient's dyspnœa increased with great rapidity; his anxious and flushed face, and great degree of distress, rendered obvious the necessity of adopting some immediate measure of relief. The operation of paracentesis was proposed, and, in consultation with the surgeons of the hospital, it was deemed advisable. At this time, percussion and auscultation conveyed the same sounds as before, excepting that the space over which percussion elicited a dull sound at the left side, was increased, indicating an increase of fluid.

October 21st.—Mr. Guthrie performed the operation, by passing a small flat trocar between the eighth and ninth ribs. The withdrawal of the trocar was followed by a gush of air in large quantity; after which, forty-one ounces of clear whey-coloured serum were evacuated. Immediate relief succeeded the operation. The heart was nearly restored to its natural position; the tympanitic sound on percussion was still distinct; respiration had returned to the upper part of this lung, and *bourdonnement amphorique* now became audible about the middle of the anterior surface of the thorax.

On visiting the patient in the evening of this day, it was found that his fever had rather increased. Pulse 140; breathing short and hurried; respiration inaudible in the left lung. The opening in the chest was enlarged, to admit of the introduction of a gum elastic tube. A quantity of air escaped immediately through the tube, followed by the discharge of about seven ounces of turbid serum. This second evacuation of the chest was likewise succeeded by a degree of restoration of the heart to its original position, and bourdonnement was distinctly audible at the anterior part of the chest.

Habeat. Pil. Sapon. c. Opio, gr. v. h. s. Acid. Hydrocyanici, ℥i. om. secundâ horâ ex aquæ cyatho.

23d.—Fever diminished; slept well; the turbid serum continues to flow in considerable quantity.

The acid omitted. Haust. Opii c. Liq. Amm. Acet.

24th.—The discharge from the wound is copious; it is obviously purulent. His respiration is easy and skin cool; he complains of irritation from the presence of the catheter; it was accordingly withdrawn.

He was ordered a draught with Sulph. Quinæ, gr. ij. and Acid. Sulph. Dil. ℥v. to be taken three times a day; and directed a nutritious diet, with bottled porter.

From this time his strength gradually declined, the purulent discharge increased, and his cough became more troublesome.

His countenance assumed an expression indicative of much distress and anxiety. Respiration is totally inaudible at the left side. *Bourdonnement* distinct at the anterior surface of the left side. Puerile respiration at the right side; less strong at the apex of the lung, over which percussion gives rather a dull sound. The voice is excessively feeble.

On the 1st of November a small quantity of warm water was injected into the wound in the chest. It produced a considerable increase in the pain and dyspnœa. The discharge increased considerably; it became very fetid. He sunk with rapidity, and expired on the 6th of November, having survived the operation sixteen days.

The whole of the left pulmonary pleura was thickly coated with a deposit of lymph of a yellow colour. The costal and diaphragmatic portions of the pleura appeared injected with numerous red vessels; eight to ten ounces of a thick puriform fluid lay in the pleural cavity.

The lung was compressed against the spine; inflation did not expand it, the air passing out through two openings on the lung's surface; one of which was situated at its apex, the other about its middle. Two or three superficial ulcerations were observed on the lung; they did not communicate with the bronchiæ. The size of the openings through which the air escaped from the lung attracted notice; that on the middle of the lung's anterior surface was about the size of a half-crown, and had jagged edges; that at the apex was not so large, and had a smooth margin. The right lung was congested; at its upper part it was indurated, and contained a number of miliary tubercles; at its apex there was a small cavity about the size of a walnut.

The lecturer commenced by directing the attention of the students to the signs upon which he had founded his diagnosis of the case under consideration. The first sign was the remarkable clear sound yielded by the percussion of the left side. This tympanitic sound was obviously attributable to the presence of a large quantity of air within the thorax at that side. The air might be contained, 1st, in a lung affected to considerable extent with emphysema; 2dly, in a lung entirely, or in great part, excavated by a large cavity; 3dly, in the sac of the pleura. The almost total absence of respiratory murmur at once proved that the lung was not affected with emphysema. The absence of any extensive expectoration, the short duration of the disease, and the early progress of the case, were sufficient proofs that the lung was not excavated by a large cavity: it was therefore reasonably to be inferred that the air was contained in the sac of the pleura.

Auscultation detected œgophony and metallic tinkling; both indicative that a liquid effusion was likewise present with the air. This opinion was further confirmed by the fact that change of posture produced a change in the sound elicited by percussion; it being dull over the most dependent part of the chest. Thus, when he lay supine, the sound was tympanitic over the whole anterior part of the chest; when he sat upright, the sound was tympanitic above, dull below. On succussion, fluid was distinctly audible, as if shaken in a large glass jar. The obliteration of the intercostal spaces, and the decubitus on the left side, were additional proofs of the presence of air and liquid effusion: it is obvious that both exist in the same cavity.

The next inquiry is as to the source of the air. 1st, it may be the product of the decomposition of a puriform effusion in the chest, as stated by Laennec; 2dly, it may appear in such a way as to lead to the supposition of its being a secretion, as mentioned by Andral, in his Clinique Medicale; 3dly, it has been known to pass into the pleura through a slough in the œsophagus, engaging the right wall of the mediastinum, and permitting the entrance of air and the liquid food of the patient into the thoracic cavity; 4thly, it may come from the lung through an opening on its surface, which may result from a wound, the rupture of an air cell, the falling out of a gangrenous eschar, the bursting of a pulmonary abscess, or of a softened tubercle.

The presence of the sound called by Laennec *bourdonnement amphorique*, from its resemblance to that produced by blowing into a cask or jar, is the strongest evidence of the existence of an opening on the lung's surface, through which the air might pass into the sac of the pleura. In the case under consideration, this sound was absent before the operation; but the rapidity, and almost suddenness, with which the left side of the chest was distended with air, and the absence of symptoms denoting a previous liquid effusion into the chest, clearly shewed, that the air was not the product of secretion or decomposition; nor did it appear that the œsophagus had been the seat of an ulceration or sloughing process: it was therefore inferred, that the air passed through an opening on the lung's surface, which communicated on the one hand with the bronchiæ, on the other with the cavity of the pleura. That this opening was not the result of a wound was evident; nor was it produced by the rupture of a dilated air cells, as was apparent from the absence of the signs usually attendant on emphysema of the lung. Many symptoms exhibited by the patient since his entrance into hos-

pital left no room to doubt the existence of pulmonary tubercles. The softening, and subsequent rupture, of one of these tubercles deposited immediately subjacent to the pulmonary pleura, were therefore set down as the cause of the pulmonary fistula—an opinion founded as well on the above reasoning, as on the known fact, that such is the mode of formation of these pulmonary openings, which morbid anatomy proves to be the most common.

The lecturer then proceeded to shew that the liquid effusion resulted from pleuritic inflammation, most probably consequent on the admission of air into the cavity of the pleura: what the *precise* nature of the fluid was, our data did not enable us sufficiently to determine; but from the observation of similar cases, we might safely pronounce it to be a sero purulent fluid.

The prognosis in this case must obviously be very unfavourable. Even supposing the right lung to be healthy, his chance of recovery is very slight. The opening through which the air now passes must be closed by the adhesive process, to prevent its further accumulation. The most likely manner in which this would take place would be by an adhesion of the costal to the pulmonary pleura, over the opening, by which the cavity of that membrane would be obliterated in a degree proportioned to the extent of adhesion. The lung, condensed by the continued pressure of the fluid, is incapable of such distention as must bring it to meet the costal pleura; the ribs are, therefore, pressed in, and a contraction of that side of the chest takes place, a deformity which has been well delineated and described by Laennec. Such would be the process of cure. The contraction of the chest is not unfrequently observed in cases of simple empyema. In such cases as this, however, the continual ingress of air keeps the two portions of the pleura so apart from each other as to prevent the possibility of their adhesion. To get rid of the air now effused, and to prevent the entrance of more, is obviously the first indication of treatment. Yet such is the unhealthy nature of the pulmonary fistula that the stoppage of it by any natural process must be considered as utterly hopeless, so that the chest will be filled again almost as rapidly as it has been emptied. The operation, then, of *paracentesis* must therefore be resorted to in this case merely as a measure for temporary relief, and as calculated probably to prolong life for a few days. Its effects are immediate in affording relief to the distressed dyspnœa under which the patient suffers. This it does by removing the fluids which distend that side of the thorax, and displace the heart, affecting, doubtless, the right lung also, by pressure on the mediastinum. The trial of this operation in cases of this affection has hitherto been almost universally unsuccessful. In some it appears to have prolonged life, (in one case, especially, related to me by Dr. Davis, of the London Hospital, the patient lived from April to December) while in others it is not clear but it has hastened the fatal result. A case of perfect cure is related by Dr. Archer, having occurred so far back as the year 1798: that it was a case of pneumo-thorax was obvious from the fact that the Doctor *heard* fluctuation in the chest; but whether the air had passed through a fistulous opening in the lung, does not appear.

Rain fallen, ·7 of an inch; of which, ·5 fell on Saturday morning.

METEOR.—On Thursday, the 13th, about a minute before six in the evening, a remarkably brilliant meteor made its appearance in or near the zenith: it proceeded in a southerly direction. The sudden transition from comparative darkness to a light equalling that of mid-day, produced an extraordinary effect upon the minds of those who witnessed it.

A friend who happened to direct his eye towards the zenith before the meteor appeared, says, that from the larger ball of light, smaller ones were discharged in various directions, for a moment only previous to its moving.

LECTURES

ON THE

THEORY AND PRACTICE OF MEDICINE;

Delivered at the London University,

By Dr. Elliotson.

DISEASES OF THE HEAD AND NERVOUS SYSTEM.

PHRENITIS.—HEAD-ACHES.

Variations in the Degree of Inflammation.—Inflammation of the brain itself and its membranes, like all other inflammations, may vary in degree from mere inflammatory headache up to the most violent delirium. There may be mere headache, characterized by a sense of tension, heat, and a degree of giddiness, or there may be simple giddiness without any pain, or watchfulness, or sleeplessness; and from these symptons you may have all the intermediate grades, up to the most intense inflammation and the most furious delirium.

Duration.—The same variations, of course, may occur also in regard to the duration of the affection. Sometimes this inflammatory affection of the head will destroy the patient in a few days, or even in a few hours, and sometimes these symptoms may last for years. Chronic inflammatory headache, which is neither more nor less in many cases than phrenitis, may last for many years. When the disease is of this chronic character, you may have merely some thickening of the membranes; but if lymph be effused, they are rendered still thicker. There may be continuous adhesions, and even the bones themselves, as well as the membranes, may become exceedingly dense and thick.

Mild Phrenitis.—To speak more particularly of the milder degrees of this affection: when it is in a very mild degree, a person complains more or less of headache, but that headache is attended by a throbbing sensation; there is a throbbing pain in the head, or a throbbing of the temples, or of some particular part, and the pain usually is the most intense in the forehead. In the greater number of cases, the patient puts his hand up to his forehead. It is rendered worse by heat—by the heat of the bed and by the heat of the fire. It is rendered worse too by stooping, and especially on rising again after stooping. This will cause a sensation of great weight, or even a cutting sensation, to be experienced within the head. It is generally worse in the morning, from the continued heat of the bed and the horizontal posture. There is likewise, in many cases, drowsiness; and yet the patient perhaps cannot sleep, on account of the intensity of the pain. There is a morbid heat of the head, and a morbid sensibility to light and sound: these produce, not an agony, but an uneasiness; the least noise frets a patient, and so does the light. The mind too, in these cases, is almost always irritable; patients are easily put out of humour, and they are impatient. You will find, in these cases, that the pain rarely extends below the zygoma. If it be an inflammatory affection within the head, of course it is within the cranium, and therefore the face does not suffer; nor does it extend, for the most part, down the back of the neck. The pain is usually not increased by touching the scalp. Now and then, however, you will have the external part affected, as well as the internal, and then there may be tenderness of the scalp, but for the most part there is not.

Diagnosis between Phrenitis and Rheumatism of the Scalp.—In rheumatism of the scalp, on the contrary, there is almost always extreme tenderness. You will find many cases where you will be exceedingly anxious to ascertain whether the pain complained

of is internal or external, and you will find, by attending to these marks, that you will be able to say it is internal; or, by their absence, to say that it is external. In rheumatism, there is not only for the most part tenderness of the scalp, but the pain generally extends beyond the cranium; it frequently runs down the face, it runs behind the ears, down the neck, and very frequently there is rheumatism in other parts. Sometimes there is great sweating, just as in common rheumatism.

Now and then, however, in rheumatism, the internal parts suffer, so that you have both external and internal inflammation; and, in these instances, the nature of the case is easily made out in general, by observing that, although the scalp is tender and the pain runs down the face and the back of the neck—although there is rheumatism in other parts and the pain is worse in the evening, yet there is likewise giddiness, drowsiness, and a throbbing of the inner part of the head. When you see two sets of symptoms like these, you may be sure that the two parts are affected, the external and the internal; and, in such a case, although you see the patient is labouring under rheumatism, yet you must not trust to such ordinary remedies as, for the most part, causes rheumatism to disappear sooner than it otherwise would; but you must treat the case as phrenitis. If you see signs of internal inflammation as well as rheumatism, then, of course, you must treat the disease so much the more actively. Very frequently this pain of the head, when it is rheumatic, is attended with a great sense of coldness; in these cases, too, the pain, for the most part, is worse in the afternoon or evening; but the latter is by far the most usual, and that without any cause which we can discover. The pain is not worse in the morning; the addition of even two or three flannel night-caps does not make it worse; but in inflammatory pain of the internal part of the head, these things could not be borne, and, as I have before said, the pain is almost always worse in the morning, which arises simply from the mechanical circumstance of the horizontal posture allowing the blood to go more easily to the head, and rendering its return more difficult, and from the bed increasing the heat of the body. But in rheumatism which is of a cold nature you will find this very pain to be almost always worse in the evening, and relieved by heat. These circumstances clearly point out the nature of the case.

Neuralgic Pain of the Head.—When pain of the head is of another description—neuralgic, you may frequently discover its nature by the absence of these internal symptoms, and by the pain running along particular nerves. Sometimes it runs in the course of the supra and infra orbital nerves; sometimes it is particularly seated in the branches of the fifth pair near the ears; and sometimes you may trace it along the mastoideus. At other times, however, it does not run along the course of particular nerves, but is situated in one spot, where there is a violent continual pain, and this is very common in hysteria. Sometimes the part itself is very tender, and sometimes not. When you see the absence of the usual symptoms of inflammation of the head, you may easily in general make out the true nature of the case. It very frequently attacks the brain on one side, not in the situation of the supra orbital nerve merely, but some other part of the brain, and the pain seems seated there. In this case it is not intermittent, does not run along the branches of nerves, but is situated in nerves terminating at one spot on the surface of the body.

A pain of this description is sometimes inflammatory, sometimes attended with these internal symptoms, and then you have to treat it accordingly. But frequently there is nothing but a fixed pain in one single spot, and it may last for a few days or for a long time, coming on at regular or irregular periods. Such a pain as this is frequently hereditary. I have known many members of the same family, children of the same family, especially after they have become adults, suffer the disease. It is a very hereditary sort of pain, a pain over the brow coming on once in three weeks, or once a month, or more or less frequently. It is sometimes produced immediately by mental agitation, by overloading the stomach, or putting improper articles into it; but, in spite of every thing, it will come on, without any apparent cause, in many persons every few weeks.

Local Pain of the Head.—But, in many other cases, you will have a local pain, a pain not intermittent, situated in different parts of the head, and very frequently it is hysterical; it occurs especially in hysterical patients.

Thus you have pain of the head of a decidedly inflammatory nature, attended with inflammation of the brain itself or its membranes. You may have pain of the head of a rheumatic nature, and the rheumatism may be active, attended with heat, or of a cold character, which I shall hereafter speak of, which is relieved by warmth, and is worse in the evening; or you may have another headache, which is neuralgic, and of that kind called *tic douloureux*, running along particular nerves, but sometimes diffused with morbid sensibility of a particular part, or of an intermittent character.

Sick Headache.—The last kind of headache which I mentioned, where it occurs parti-

cularly over the brow, has been called *sick headache*, because it is attended frequently with sickness. The stomach is deranged in the first instance, or it soon becomes deranged after the headache has begun; you find, more or less, headache connected with the affection of the stomach, so that it is called sick headache. I believe that most persons ascribe this to the stomach; but I am quite sure it is very unjust to lay it to the charge of the stomach in every case. The stomach has enough to do with diseases of its own without being accused of the diseases of other parts. I am quite sure of this, because I have experienced pain of this description two or three times from evident local causes in the head. From having a draught blow on my head when I have been overheated, I have had intense pain come on. I may mention that I rarely have any thing the matter with the stomach; but, after this pain has existed some time, I have had violent nausea, and then vomiting, the stomach being only affected sympathetically. I have observed too, in a great number of persons, that this headache has not been preceded by an affection of the stomach. People have declared that they digested well, that they had a good appetite, not only up to the time of the occurrence of the pain, but as long as the pain was moderate; but, when the pain arrived at a certain intensity, then the stomach fell into nausea and vomiting, and was disturbed as much as the head. There is no doubt that persons predisposed to these pains may bring them on by overloading the stomach, or taking improper articles of diet; but it is to be remembered that pain of the head will cause disturbance of the stomach, and therefore we have no reason to suppose that the stomach is in fault. I do not think that you ought to infer that the stomach originally is in fault, simply because it is disturbed as well as the head. In a great many cases, the stomach is not affected until the derangement of the head has arrived at a certain point; but the state of the stomach will bring it on, and so also will costiveness; but it is precisely the same with all other affections of the head and alimentary canal. If a person allow himself to become costive, he will he almost sure to have an inflammatory headache, and an inflammatory headache will induce costiveness. It is quite illogical to say that so many affections of the head arise from the stomach and intestines, and it is just as wrong to say that all affections of the alimentary canal depend on the head; yet there are parties who, if they do not say so in plain and distinct terms, they nevertheless approximate very closely towards it.

As I shall not have another opportunity of speaking of this sick headache, I had better say that it is a most intractable complaint. I have known many persons have it in whom all the remedies that were employed failed in accomplishing any material good. If the system be too plethoric, if you find the pulse full, if you find them eating and drinking too much, you may do good to a certain extent by lowering their diet and bleeding. Now and then the pain is so intense that a degree of phrenitis occurs, and you must then treat it as phrenitis; but where it only comes on from time to time, I do not think that you will easily remove it, though you may lessen it and prevent it from being as bad as it otherwise would. If the patient avoid every thing which is likely to do him harm, and pays proper attention to his bowels, this object may be affected. Now and then the stomach is very much out of order, and an emetic may mitigate urgent symptoms; but it will not produce material benefit. I have tried iron, sulphate of quinine, arsenic, and every medicine that suggested itself to my own mind, or has been recommended by others, but it has been in vain. After a number of years this description of headache will sometimes cease of its own accord.

General Treatment of Phrenitis.—As to the general treatment of phrenitis, that is perfectly easy. In the first place you should have recourse to copious blood-letting, and my own experience leads me to think that bleeding in the arm is just as good as bleeding in the neck. It is not advisable to bleed from the temporal artery, because you have to put a bandage on the head afterwards, which occasions more or less augmentation of the heat, and the bandage itself is often very troublesome. Then with regard to opening the jugular vein, that sometimes causes so much agitation of a patient that it is not a very easy matter to accomplish it; but there is no difficulty in detracting blood from the arm. But notwithstanding all this, I am not aware that there is any particular advantage in taking blood from the head; if you make a large orifice in the arm, make the patient stand upright, and produce a strong impression: that will generally answer every purpose. Cold should be applied to the head, but blisters are dangerous things. A bladder of ice laid upon the head, or a stream of cold water allowed to run upon it, are both very serviceable. In a case of violent phrenitis, evaporating lotions are hardly sufficient, and it is better to apply ice, or a stream of cold water. The posture of the patient should be carefully attended to. The head should be raised as much as possible, and silence and darkness are indispensible. I need not say that active purging is likewise required, and you may give antimony, colchicum, or mercury. I certainly

would not give digitalis in such a case, for it is a narcotic that frequently produces irritation of the brain when exhibited for other affections, and not only so, but it is much less to be depended upon in inflammatory cases than other medicines: it will, moreover, frequently produce delirium or headache. Antimony is a very good remedy if you give it so as to keep the patient in a state of constant nausea; colchicum, likewise, is excellent, on account of its depressing the whole system, producing nausea, and purging the patient violently. But altogether, as I said when speaking of the treatment of inflammation in general, I should place the greatest reliance on mercury, and get the mouth sore as quickly as possible. Sinapisms to the feet may likewise be exceedingly useful; and after free bleeding, a blister applied to the nape of the neck may be advisable; and after a time, if the inflammation be not very violent, a blister may be applied to the forehead; but it is not till towards the close of the disease that I would recommend any blisters to be applied to the crown of the head. I need not say that the patient ought to be starved, and that rest should be strictly enjoined. If the disease have arisen from the cessation of another disease, we ought, if possible, to re-excite it. If it have arisen from the cessation of gout or rheumatism, we ought to apply sinapisms to the extremities, to re-excite them.

In chronic inflammatory headache the same treatment is required, but carried on, of course, with less vigour. It is astonishing what perseverance in bleeding is sometimes required in order to effect a cure in these cases; you must bleed every week or ten days, either from the arm, or by cupping, or by leeches. The application of cold, of blisters to the nape of the neck, and to the forehead, and likewise setons in the neighbourhood of the neck, are all useful. You will find the disease continually give way to the exhibition of mercury as soon as the mouth is tender. I have seen this in dozens—I might almost say hundreds of instances—bleeding did good to a certain extent only, but as soon as the mouth became sore, away the pain went. Low diet, and attention to the state of the bowels, I need not insist upon.

I must, however, mention that in some cases which have proved rebellious to starvation, the application of cold, setons, frequent bleedings in various ways, and ptyalism, long continued, I have seen the disease yield rapidly on taking away blood from a more distant part. I have seen several cases in which, on applying cupping-glasses no longer to the nape of the neck, but to the hypochondrium, and some say to the verge of the anus, the disease has rapidly given way. I have myself been surprised on some occasions to see the disease decline immediately when cupping was instituted on the abdomen.

You will find the same perseverance in bleeding frequently necessary when the phrenitis or inflammatory state of the head is not characterized by pain, but simply by giddiness. I have seen some cases of intense vertigo in which there was sufficient strength of body to bleed freely, ultimately give way to that measure. In instances where I could not make out any sympathy with the stomach and intestines, but where it appeared to be an inflammatory state, the chief symptom of which was vertigo, or where that was almost the only symptom except throbbing of the head, on motion, or taking stimuli, I have seen continued depletion effect a cure. If patients feel themselves worse for stimuli, and you find the pulse sufficiently strong, I would certainly bleed. I recollect a case of severe vertigo in a young man attended by no other symptom whatever; and as he was young and strong, I bled him to between twenty and thirty ounces with no relief whatever, but with no aggravation of the symptoms, and I was obliged to have recourse to this extensive bleeding several times before he was cured. He had been ill from this giddiness for many months, and used to roll about the room with it, but he recovered simply by repeated bleedings to this extent. It is just the same sort of case as chronic inflammatory headache, only that these symptoms arise from the particular part of the head which the inflammation has attacked. I had a case only the year before last in which this vertigo was acute. A young woman was suddenly seized with intense giddiness, but without any pain. There were some very odd symptoms about her. Her eyes were pushed far more forward in the orbits than in health, and every event appeared old to her—so that there was an extraordinary affection of the brain. If she put down a tea-cup, she fancied that it was years ago, and she could not get over this feeling. These were her symptoms; and as she was plethoric, and her pulse justified bleeding, she was twice depleted very copiously, and by that simple means, together with purging, she got completely well. There was no pain whatever in this affection.

It is, however, to be remembered that all these affections, whether there be an inflammatory state of the head, or inflammatory headache, or simple vertigo, may depend upon an opposite state of the brain. I have seen several cases of chronic pain of the head which have resisted all anti-inflammatory treatment, but which gave way very speedily to the exhibition of iron,

quinine, or other tonics, and to full diet. You can only judge of these things by observing, not only how long the case has existed, but that the pulse is feeble, and that stimulating the patient does not make him worse. If this be the case you may safely resort to an opposite mode of treatment, and I believe iron is the best remedy you can employ. In other cases it is well to apply cold, in the form of a shower-bath, which is a powerful tonic. This state appears to be a morbid sensibility without any great accumulation of blood, and certainly without any violent action of the brain. With respect to vertigo, I recollect seeing a gentleman last year who had a constant sensation as if he were going to fall forwards—a sense of plunging as he sat in the chair; he had no pain at all, but he had heat, and the throbbing sensation in his forehead was terrific. He was upwards of 60 years of age, but he had a florid complexion, and was a strong old gentleman. It seemed to me that the case required antiphlogistic treatment, and I recommended that it should be put in practice, and that his diet should be low. I may mention that he was a very excitable person; that although he was so old, he said he had not lost any of his vigour; that since he was 25 he had not experienced the least change; that in hot weather he experienced the strongest excitement. In general people are not so sensitive at that age, but the slightest effects of various agents were distinctly perceptible to him; in fact, such as would not have affected other individuals. Seeing all this, and that there was such extraordinary excitement within the head, I concluded that though he had no pain, yet the case was certainly of an inflammatory nature. Antiphlogistic measures were put in practice, but I understood without the least benefit. He was afterwards allowed meat, wine, and stimulants of all kinds, and I was told that he got perfectly well. Here was an instance of vertigo of an opposite kind. It was difficult for me to form an opinion, though I had paid great attention to these diseases, and I formed a wrong judgment. I thought antiphlogistic treatment would be best, and it is possible that the other mode might not have succeeded if anti-inflammatory treatment had not been put in practice first.

You will have inflammatory pain of the head of a nature to be benefitted rather by stimulants and tonics than by depletory measures, and you may have these partial symptoms of affection of the head, such as vertigo, which must be treated in the same way.

Now it is to be remembered, that after the acute disease you may have a state in which nourishment, and even opium, are the chief remedies. At the close of phrenitis, especially if you have evacuated well, there sometimes will be a continuation of delirium; and if you evacuate still more, you will kill the patient; and sometimes this state will come on without any previous active inflammation. In such a case as this opium is the proper medicine, and for the most part the patient's diet must be good; but of this I will speak hereafter, when I come to consider the next class of diseases of an inflammatory nature which occur within the head. It has been called *delirium tremens*; and as it has received a particular name, I will speak of it separately; but it is a state which will occur without any great tremor at the close of common inflammation of the brain.

HYDROCEPHALUS ACUTUS.

There is another instance of inflammation of the brain, which, from its causing, for the most part, great effusion, and this effusion having formerly been noticed more than any thing else, the disease goes not, or has not gone, by the name of inflammation of the head, but has received the peculiar appellation of *Hydrocephalus acutus*. Some, who have been more precise in their language, have chosen to say *hydrencephalus*; and some have called it *phrenitic-hydrocephalus*.

This is a disease seen, in the greater number of instances, in children; in fact, it particularly occurs in the phrenitis of children, but the phrenitis of adults is sometimes attended by a very copious effusion. When a child has inflammation within the head, it usually goes by the name of "hydrocephalus acutus," but in its essential character it is very much the same as the common phrenitis of adults.

Premonitory Symptoms. — It frequently comes on in children after premonitory symptoms—after heaviness of the head, dullness of the mind, and a disturbance of sleep; and the child too, frequently has frightful dreams, wakes screaming, and is found to be restless both up and in bed—to be exceedingly peevish in temper, and there is a continual knitting of the brows. I may mention that the last is a common symptom in inflammatory states of the head. The child, too, frequently is observed to walk insecurely—to totter a little, as if it experienced a certain degree of vertigo. Some say they have observed children, under these circumstances, have a great trick of putting their hands behind their head, and pulling the back of their neck. There is occasionally darting pain in the head, and of course there is feverishness. The body is hot, and the pulse is quick and exceedingly various. You will observe, too, that from the feverish-

ness the child picks his nose and lips; the nose and lips are dry, and this gives rise to a degree of itching, so that the child is continually picking its nose and lips. Of course there is thirst and loss of appetite, and frequently there is a fœtid breath. The stomach and bowels are disturbed; the tongue is white, yellow, or brown; nausea is experienced, and also vomiting and costiveness—though occasionally there is purging and griping. The fæces are observed to be white, and to have a sour smell; but, on the other hand, they are sometimes dark and very fœtid. The abdomen is frequently full, especially at the epigastrium, and there is frequently tenderness on pressure; but this is particularly noticed at the epigastrium and the right hypochondrium.

Now these premonitory symptoms may go off spontaneously, and if the practitioner attend to them he may remove them so that nothing follows. Whenever we see such symptoms as these, we must recollect that they may be easily followed by hydrocephalus, and it is our duty to attempt to remove them, which we may generally accomplish; but if we fail, and hydrocephalus does come on, we have, at any rate, done our duty. It is true that hydrocephalus might not have supervened, but it was impossible for us to tell that, and it is our business to do what we can to prevent it. These symptoms may last only a day or two, and then come on with increased severity; or they may last many weeks; and the continuation of these symptoms has been detailed by Dr. Yates, who terms them the premonitory symptoms of this disease. In fact, he directed the attention of the public to these circumstances, under the idea that the disease might be prevented.

When the disease, however, is formed, it has two stages; and it may occur without any premonitory symptoms at all. Not only may they vary in duration—from a day to a few weeks—but they may last only for an hour or two; and, indeed, they may not exist at all: the child may be seized in a moment.

Symptoms in the First Stage.—When the disease occurs, there is severe pain in the head—shooting through it; so that the child lays its head in its mother's lap, and is continually crying, "Oh, my head!" It is awakened, too, from sleep by this violent shooting pain in the head; the head is found to be very hot, and there is an intolerance of sound and light, and, from the sensibility of the retina, the pupil is very much contracted. From the extreme irritation, I presume, of the nerves, there is strabismus; but some ascribe this to a paralysis of certain nerves, so that some muscles get the ascendency over others; however, you will see it before there are any signs of paralysis—you will see it during the mere excitement of inflammation. Besides the squinting, there are convulsive spasmodic motions of other muscles, and frequently there is general convulsions. Sometimes there is at last, but sooner in some cases than in others, delirium; and the delirium may not be constant: in the first instance, it is not constant. The child is observed to turn its head continually about on the pillow, never to be at ease, and there is a peculiar motion of its arms; so that it saws the air with its hands, and tosses them over its head. Whenever you observe these symptoms, you may be sure that the disease is formed.

There is now violent pyrexia; the pulse is rapid and full; and Golis, a physician at Vienna, who has the care of an establishment for infants there, says that the abdomen sinks, and becomes flatter, and that this is a pathognomonic sign of the disease, so that if this occur, you may be certain as to the nature of the disease; but whether he is correct I cannot tell. There is, in this stage, costiveness; and the stools are usually very fœtid and of a very dark colour, something like tar. About this time, the abdomen (especially the epigastrium, or the right hypochondrium) is exceedingly tender, and the vomiting which occurred as a premonitory symptom is now perhaps very frequent. These symptoms, like the premonitory, may exist for various periods; but, of course, they cannot exist so long as the premonitory symptoms may. They may last only a few hours, or they may last a day or two; or they may be extended to seven days, but I believe they very seldom go beyond that.

Symptoms in the Second Stage.—After this, the second stage comes on; which is that of exhaustion. There is more or less blindness now, and the child is unable to discern one object from another; and perhaps it cannot perceive the light, which is now borne very well. There are no longer twitches, and the pupils are no longer contracted, but dilated; sound no longer produces disturbance, but appears not to be heard. There is a general insensibility, and the child, from being delirious and irritable, is now drowsy; and the convulsions come on with more intensity, as likewise does the squinting. The pulse is no longer quick, but weak and slow; and, in fact, an apoplectic state occurs. There is sometimes hemiplegia, or local paralysis of the limbs; and there is likewise paralysis of the eyes. Sometimes you will see the two stages marked very distinctly, but they certainly run into each other: you see one running gradually into the other, so that both may exist together in a limit-

ed degree; and this may last for three weeks, but it rarely, I believe, extends much longer. The first stage does not subside entirely, but there is a great diminution of it; and the second stage comes on, but is not fully formed. The first stage without the second, rarely extends beyond seven days; but when the second stage begins before the first has come to a close, the two may continue together for two or three weeks. Now and then the pulse is quick throughout the disease; and when the apoplectic state comes on, the pulse is as rapid as before, or very rapid.

Symptoms in the Third Stage.—It has been observed, that before death, after the second stage has been fully formed, there are again symptoms of excitement; so that some writers have divided the disease into three stages: but this, I believe, does not occur very frequently. Now and then, however, there is excitement, and the pulse, after it has been slow, will become quick; there will appear to be some sensibility of the eyes and ears; even the muscular powers which have been implicated will be restored partially, and likewise the mind; so that not only the delirium but even the stupor will pass off, and the child again knows its friends and parents. Some of these symptoms will occur without the others. Occasionally the mind will be restored to a certain extent, and the senses restored, and yet the pulse will continue low. Now and then the pulse will be rapid, and no other change occur. But now and then this excitement will occur before death—this restoration of the powers of the mind and the powers of volition in the muscles, will take place where great effusion is found after death, and where there is every reason to believe that effusion existed at the time that this restoration occurred. The common people term this "a lightening before death;" and you will observe in many diseases an apparent amendment just before the fatal event. But when this last change does occur, the pulse, for the most part, becomes very rapid; and for the most part, whatever restoration there may be, there is more or less stupor observed, and perhaps still convulsive actions.

The disease occasionally occurs in a moment, and when that is the case, from the idea of water being so prevalent among medical men, it has been called, by Dr. Golis, *wasserschlag*, or water-stroke. But it is to be remembered, that you see children die from this disease without effusion taking place; and on that account, the name of *arachnitis* would, I think, be much better than hydrocephalus. I believe I mentioned, when speaking of inflammation, that sometimes, in a moment, a child will have a rush of blood to the head—that it will breathe hard, and die; and afterwards, a great collection of blood may be found in all the vessels of the head.

The disease sometimes, when it terminates, leaves more or less paralysis; sometimes it will leave hemiplegia; and some patients have recovered with the loss of one arm or one leg.

LECTURES

ON

DISEASES OF THE EYE,

Delivered at the Birmingham Eye Infirmary,

BY RICHARD MIDDLEMORE, ESQ.

PURULENT OPHTHALMIA IN THE ADULT.

PURULENT ophthalmia, or inflammation of the conjunctiva producing a discharge of purulent fluid, may be conveniently considered, as it takes place in the adult and in the infant. We shall first consider it as it occurs in the adult.

The symptoms which indicate the commencement of this disease are, a slight tingling and stiffness of the lids, and an itching or smarting sensation at the corners of the eye, which induces the patient to rub it. Persons in this state will tell you that the eye feels hot and dry, and that the movements of the lids upon its surface occasion some uneasiness. This sensation of uneasiness will very soon be superseded by severe burning pain, and they will complain as if sand or particles of dust were beneath them: at the same time there will be a slight increase of vascularity, and a profuse flow of scalding tears, with some intolerance of light; the eyelids will be swollen, and their margins will be red and irritable; the inner surface of the inferior palpebra will generally be found in a highly injected state. The preceding set of symptoms is quickly succeeded by the following:—The pain is now of a severe and throbbing character, and is not always limited to the eye, but sometimes extends to the head and face, producing, if one eye only be inflamed, intense hemicrania and facial neuralgia: there is a sense of tension of the globe; the conjunctiva presents an almost uniformly red surface, and is raised in various degrees in different instances around the cornea; the eyelids are tumid, and their edges, and still more their angles, are extremely red and irritable; the patient cannot bear the smallest quantity of light; there is an abundant secretion of purulent fluid, which requires to be

frequently removed, as, if allowed to remain, and the lids are closed, it collects beneath and painfully distends them. This fluid is at the commencement of the inflammation very thin, and of a pale yellow colour, which frequently becomes heightened, and its consistence increased, until it is a thick straw-coloured fluid, and finally this secretion becomes blended with serous, sanious, or sanguineous fluids. You will generally find the degree of inflammation indicated by the colour and density of the discharge: it will be pale and thin, if the inflammation be slight, and more consistent, and of a deep yellow colour, if it be severe. You would apprehend mischief, independently of an examination of the inflamed eye, as soon as the discharge became blended with the thin fluids just mentioned. If the inflammation be not now checked it will spread to more important textures, and be indicated by the symptoms peculiar to its extent and complication: the cornea also will participate in the mischief; its brilliancy will be destroyed, and it will assume a pale, dingy ash colour, and will eventually slough or burst, and permit the escape of the contents of the globe, when the pain and other severe symptoms will usually subside; or it may happen that the membrane of the aqueous humour may remain entire, projecting as a pellucid tumor through the corneal aperture, and preventing the transit of the humours; or the lens may be prevented from escaping by the small size of the opening in the cornea, and thus give rise to a deceptive expectation on the part of the patient as to the preservation of his sight; for, on the destruction and separation of a portion of the opaque cornea, the light will pass through the humours, whose transparency has not been materially injured, and for a short time vision may be distinct; but this state will be of very brief duration, for, sooner or later, the humours must be discharged, if the opening in the cornea be considerable; or, if not, the discharge of the aqueous humour and consequent prolapse of the iris, combined with the opaque and ulcerated state of the cornea round the opening, and very probably closure of the pupil, will altogether prevent, or materially interfere with, vision. Such a patient may indeed recover a certain degree of sight, but it will only be sufficient to interfere with the vision of the opposite organ: it were better that collapse of the eye-ball be permitted to occur, so that an artificial eye may be worn; the deformity will be then diminished, and the obscurity of vision occasioned by possessing two eyes of very different degrees of visual perception prevented. If, however, the ulcer of the cornea be small, or, if extensive, superficial, it may, in the one case, be filled up by lymphatic deposition, and, in the other, replaced by an adventitious structure, and, in both instances, there will exist an extensive opacity, which in many cases cannot be removed; the pupil may, however, be drawn by natural efforts quite away from the opaque part of the cornea; or, if not, there will probably be space enough for the formation of an artificial pupil.

It may happen that the palpebral portion of the conjunctiva may alone be affected at the commencement: you will be apprised of this by the great tumefaction of the lids, (which are, in many instances, so much thickened and swollen as to protrude externally, giving rise to the most painful form of ectropium) the extreme vascularity of their mucous surface, and the absence of much redness of the eye-ball and extreme intolerance of light.

It is not necessary for me to detain you long by stating the kind and degree of constitutional symptoms you would meet with in such cases; they would vary with the peculiarities of your patient, the stage of the disease, and the severity of the local symptoms. Of course you would not expect a patient to be suffering from those occurrences immediately preliminary to sloughing of the cornea and suppuration of the eye-ball, without also experiencing considerable constitutional disturbance; there would be in such a case irritative fever and general derangement of the health, and you would bear this in mind in determining your means of cure, not forgetting, however, their cause, regarding, as of secondary importance, the constitutional affection resulting from such cause to which I have just alluded.

Now there is a mild form of this disease sometimes very prevalent among children, producing no important symptoms and requiring no active treatment; it would appear to be readily disseminated by the contact of matter from the eye of one child to that of another, aided by disordered health, a damp state of atmosphere, and want of cleanliness and good nursing; for if you will direct their parents not to allow the linen or sponge with which the diseased eye is bathed to be used for any other purpose, and enjoin the strictest cleanliness, and attend to the state of the bowels, you will generally banish it: it does not usually attack those children who are well nursed and whose constitutions are vigorous and robust.

Effects of Purulent Ophthalmia in the Adult.

The effects produced by the purulent ophthalmia of adults will be decided by the severity of the inflammation, the time at which it first engages medical attention, the mode in which it is treated, and the

existence of constitutional peculiarities or idiosyncracies. If your treatment be judicious, and the disease have only just commenced, you would expect to remove it entirely, without leaving behind any functional or structural mischief; but if, on the contrary, you were not called to such a case until the disease had advanced to the production of ophthalmitis, attended by active inflammatory chemosis, you would not, in many instances, be able to prevent some of its worst consequences, namely, sloughing of the cornea and suppuration and collapse of the eye-ball; if, however, by the employment of active remedies, you were capable of subduing the severe symptoms, you would expect the occurrence of a certain degree of opacity of the cornea; that is, admitting your ability to prevent the ulceration of the cornea (of which, in many instances, the opacity is a consequence) from extending through the whole of its layers. Should this latter occurrence take place, there may be adhesion of the iris to the edge of the ulcer (synechia anterior); or the iris may be drawn together where formerly the pupil existed, forming closed pupil (atresia iridis completa). If the chemosis be severe and long-continued, you will probably have to encounter a chronic state of ophthalmia, and afterwards a granular condition of the conjunctiva. Sometimes the pressure of the tumid palpebral and sclerotic conjunctiva upon each other produces ulceration of the points of contact, ending in permanent adhesion of those surfaces, unless you are careful to prevent this effect by frequently separating the lids when such mischief seems likely to occur; and even then you will generally have a cutaneous state of the conjunctiva, with a slight degree of ectropium: the tumescence and thickening of the conjunctiva may remain and produce ectropium, requiring the treatment adapted to the cure of that disease; or, lastly, the conjunctiva may be studded with small tumors (fungous excrescences), which may require excision with the scalpel; indeed many writers appear to imagine that pterygium is sometimes produced by this disease; but I am not prepared to accede to the accuracy of this opinion.

Another very frequent effect of this disease upon the palpebral conjunctiva is a vascular, tumid, and unequal state of its surface. But I shall not enter upon a minute statement of the pathological conditions of the palpebral conjunctiva, as excited by this disease; they are many and various, and not unfrequently leave behind a state of ectropium, and induce opacity and vascularity of the cornea, and, if allowed to continue, very often lead to the irreparable destruction of vision. This state of things was particularly remarked in that form of ophthalmia which has been rather vaguely termed Egyptian.

These are nearly all the modes in which this disease terminates that I am acquainted with, and you will learn from their variety and importance the necessity of promptly subduing those acute symptoms, the continuance of which is liable to be followed by effects so injurious, and, in many instances, so destructive, to vision.

Diagnosis.—Purulent ophthalmia has a certain degree of resemblance to catarrhal and to gonorrhœal inflammation of the conjunctiva. I have already entered pretty fully upon the means of distinguishing the former from purulent ophthalmia. Gonorrhœal ophthalmia may be distinguished from purulent by the nature of its cause, the great degree of chemosis which attends it, and also by the extreme tumefaction of the eye-lids. It has been said that the colour of the discharge will materially assist your diagnosis, and you will not certainly remark that thin pale appearance of the secretion at the commencement of acute gonorrhœal which is observed at the onset of purulent ophthalmia; but then it must be remembered that there are certain varieties, or, if you prefer it, certain degrees of gonorrhœal ophthalmia, the mildest of which are scarcely to be distinguished, as respects this quality of the discharge from the conjunctiva, from that accompanying the acute purulent inflammation of that membrane. Gonorrhœal, in short, is distinguished from purulent ophthalmia by its origin from gonorrhœal contagion, its greater degree of chemosis and tumefaction of the lids, the consistence of the discharge at the commencement and close of the disease being nearly the same; the extreme degree of deep-seated pain of the eye-ball and head, and by the destructive tendency of the disease. Purulent ophthalmia, as compared with gonorrhœal, is attended with a less degree of chemosis and palpebral swelling; there is less discharge, and also less deep-seated pain of the eye-ball, and seldom any great degree of hemicrania. The colour and consistence of the puriform secretion is variable in the different stages of the disease; it is more generally manageable by treatment, and, when contrasted with the results of gonorrhœal ophthalmia, it is much less frequently fatal to vision.

Prognosis.—If you are called to a case in which the chemosis is not very great, nor the pain intense and deep-seated, nor the transparency of the cornea much impaired, you may expect to preserve the eye with merely a slight and perhaps only a temporary impediment to vision; but if the pain be considerable, the cornea cloudy, and the chemosis great, you may apprehend serious injury to vision;—and if the

chemosis nearly concealed the cornea, which, as far as could be judged, was of a dull ashy colour—and if the tension of the eye-ball, and the sense of pain and throbbing, were severe and deep-seated—you would relinquish every hope of saving any useful degree of sight, and be prepared to expect the occurrence of sloughing of the cornea or suppuration of the eye-ball. Such are the chief circumstances which would determine the character of your prognosis, although many other events would very properly modify your opinion respecting the result of any case of this nature—such, for instance, as the state of the individual's health prior to the attack, his constitutional peculiarities, and his capacity to bear the necessary treatment.

Causes.—In reading the accounts of the Egyptian ophthalmia*, you will remark the great severity of its symptoms and the very destructive extent to which it frequently proceeded; but there are no circumstances connected with its origin, its symptoms, its mode of termination, or the treatment required for its cure, which render it probable that it differed in any essential particular from the purulent ophthalmia which we are now considering, in its severest form. There are, indeed, many circumstances connected with the soil, the atmosphere, and the physical and moral condition of the sufferers, which favoured its extension and increased its severity; but the same things exercise an important influence over every other form of disease; and I apprehend we ought not to consider mere degree of disease to alter its nature. Surely iritis, or conjunctivitis, are not otherwise than the maladies their names import, because they may chance to be unusually severe.

If you refer to those authors who appear to have paid the greatest attention to the Egyptian ophthalmia, and who, owing to their residence among the affected troops, had ample opportunities of observation, you will find that they either directly or indirectly admit the agency of many circumstances in producing, aggravating, or rendering susceptible of the disease. They do not contend that the unaided operation of contagion, and it alone, gave rise to the ophthalmia during any period of its most fatal prevalence, but, on the contrary, admit the assistance that cause derived from other agencies, and also that, in many cases, it appeared to originate where the existence of contagion was extremely doubtful, and, in some instances, apparently impossible. You will find that the earliest symptoms of the disease (as described by those who had the management of the diseased troops in Egypt and in various parts of England) were a sensation of sand beneath the lids, and a well-marked vascularity of the mucous lining of the lower lid; and if you will carefully peruse the observations of the medical attendants of the troops abroad and at home, you will be satisfied that the identity of the disease with which both were affected is most satisfactorily proved*.

The Egyptians are in the habit of tying a bandage over their eyes at bed-time, during the prevalence of this ophthalmia, with a view of preventing the ill effects arising from a damp state of the atmosphere, and possibly also to screen them from the hazard of contagion, which, from the occasional very great prevalence of this disease, is very generally incurred at such seasons; and this precaution is strongly recommended by some gentlemen who have very well described the Egyptian ophthalmia and its mode of treatment.

In order to decide the fact of the contagious or non-contagious nature of purulent ophthalmia, a gentleman named Machesy, who had resided with the troops in Egypt during the prevalence of that severe disease, applied a piece of linen well soaked in the secretion from the eyes of three patients who were suffering from this affection, and afterwards walked out a mile or two, a sirocco wind blowing in every direction. He reapplied the soaked linen on his return, and wore it during the night, occasionally moistening its surface and pressing it to the eyes, to ensure its contact with their mucous surface; but no severe inflammation followed†. Nothing satisfactory, however, is proved by an experiment of this kind.

I have known nurses affected with purulent ophthalmia from syringing the eyes of adult patients suffering from purulent ophthalmia; a portion of discharge from the eye of the latter having come in contact with that of the nurse. A similar accident has occasionally happened to medical students, and this occurrence has been observed by Mr. Macgregor and many others; and I have also known the discharge applied to the eye of a healthy individual, who was engaged in the per-

* See the third, fourth, and seventh volumes of the "Edinburgh Medical and Surgical Journal."—"An Account of an Ophthalmia which appeared in the second regiment of the Argyllshire Fencibles in 1802; with some Observations on the Egyptian Ophthalmia." By A. Edmonston, M.D.—"Attempt to investigate the Cause of the Egyptian Ophthalmia; with Observations on its Modes of Cure." By George Power.—"An Account of the Ophthalmia which has appeared in England since the return of the British army from Egypt." By J. Vetch, M.D.

* See, in addition to the authors I have previously referred to, some Observations by Mr. Macgregor, in the third vol. of "Transactions of a Society for the Improvement of Medical and Chirurgical Knowledge."

† Edin. Med. and Surg. Journal, Oct. 1816, vol. xii.

formance of the same duty (syringing the purulent eye of a patient), without being succeeded by any inflammation: he has complained of smarting at the moment of contact, but it has soon subsided, and has not been followed by any other unpleasant sensation.

On the whole, my inferences would be these:—First, contagion alone will not, except in very rare instances, produce this form of purulent inflammation of the eye, but requires to be aided in its operation by many other causes; of which we may enumerate, constitutional susceptibility or aptitude, want of cleanliness, disordered health, exposure to a brilliant sun, or to the damp night air, or to dust, or peculiar conditions of the atmosphere—the dense moist atmosphere being most prejudicial. All or any of these circumstances will generally ensure the operation of contagion. Secondly, purulent ophthalmia may arise without the aid of contagion—as occurs in many instances of relapse, and in some of those cases in which one eye becomes affected as soon as the other has nearly recovered; and, finally, the disease has occurred to a ship's crew during their voyage, whose eyes were not affected at the time they commenced their voyage, nor until some time afterwards, and who had no communication with the men of any other vessel until the completion, or nearly the completion, of their voyage. Let me not forget to mention that many persons apply for relief who are suffering from purulent ophthalmia in its most severe and unequivocal form, and who are quite unconscious of having, for a long time previous to the occurrence of the inflammation, seen or associated with any one affected with a similar disease.

If you will read the statement of Mr. Peach, in the fourth volume of the Edinburgh Medical and Surgical Journal, you will find that those men suffered most severely from purulent ophthalmia whose health had been disordered by irregularity and intemperance, and who had been long exposed to the influence of a brilliant sun and the injurious agency of keen winds.

A damp dense condition of the atmosphere will not only act as a cause, but will also materially favour the extension and aggravate the symptoms of purulent ophthalmia; even admitting that it is excited by some other agent. Many patients experience the influence of such changes in the state of the weather most severely; and we have frequently opportunities of witnessing an exacerbation of the disease, when it was nearly removed, from no other cause than the changed condition of the atmosphere. Dr. Vetch relates a very remarkable fact in illustration of this: he says, "the disease had been disseminated at the Riding-Street barracks by the 54th regiment of foot, but had not produced a single instance of its violent form until the 24th of September, when, after a very heavy fall of rain during the night, *to which the men affected with the ophthalmia were more particularly exposed*, by being at the time under canvass, the whole number of patients, to the amount of thirty-four, were found in the morning with their eyes completely closed by the swelling of the palpebræ, attended with the excruciating pain, the purulency, and other symptoms of the disease, in its most alarming and inveterate form."

Treatment.—You should be guided in your treatment by the symptoms of each particular case: nor should you let any rule which may be laid down by authors, however eminent, supersede the exercise of your own judgment.

If the symptoms be severe, and the patient tolerably strong, bleed until the pain is relieved, the chemosis diminished, and the sense of tension and throbbing removed; and afterwards apply a quantity of leeches close to the tarsal margin of the lower eyelid. You will thus relieve the state of congestion or local vascular fulness which is usually present, and at the same time, remove that state of the system which would be likely to maintain or reproduce it, and thus prevent the distention of the blood-vessels, which, if long continued, generally destroys or much weakens their tonicity, and thus lays the foundation of those chronic diseases with which, after acute inflammation long continued or inefficiently treated, the eye is so liable to be affected; and also disposes that delicate organ to frequent relapses of acute inflammation, from causes totally inadequate to produce them if the eye be in a healthy and unimpaired state at the time of their application. Whilst upon this subject, let me not forget to mention that scarifications have been much recommended, particularly at an early stage, as being an excellent mode of relieving the vascular plenitude of that part in which the disease is first evinced, and from which it frequently extends. Dr. Edmonston says, "I am firmly persuaded, that if there be any means of arresting the progress of inflammation in that violent and destructive variety of ophthalmia (the purulent), it is scarification of the vessels on the globe of the eye itself; and when performed early, and duly repeated, I have *never* known it fail of success." When you reflect that this mode of relieving the inflamed organ in one of the most acute diseases to which the human eye is subject, is recommended almost to the total exclusion of general bleeding, you will not fail to recognize the author's enthusiastic fondness for a fa-

vourite remedy. Let me advise you not to employ scarifications unless the chemosis be considerable, however great may be the vascularity of the conjunctiva; for such a mode of practice will not only betray a blind reliance on an unimportant means of cure, and thus tempt you to be less attentive to more valuable means of relief, but also inflict much pain, and excite great irritation on the scarified surface. If, however, the chemosis be considerable, you would of course freely scarify the chemotic surface, not with the view of superseding general depletion by lessening vascular fulness, as stated by Dr. Edmonston, but with the intention of preventing sloughing of the cornea, suppuration of the eye-ball, and the many evil consequences upon the conjunctiva which have been previously mentioned.

You must keep the bowels well relaxed, suiting your medicine for this purpose to the general habit and other circumstances of your patient: pills composed of the blue pill and the compound extract of colocynth, with sometimes a small quantity of tartarized antimony, have proved very useful in my own practice.

With regard to local applications: generally speaking, the common alum wash, or goulard water made twice its usual strength, will answer the purpose; but it may be necessary to use remedies possessing more soothing qualities. There are surgeons who prefer the use of strong local stimuli at the commencement of the disease: a strong solution of the nitrate of silver, the tinctura opii, and the undiluted liquor plumbi acetatis, have had their respective advocates; and I have previously informed you, that Mr. Guthrie is in the habit of using a strong ointment, composed of the nitrate of silver mixed with lard, or the unguentum cetacei, in nearly every form of inflammation of the conjunctiva, attended with increased discharge from its surface, at the commencement and at almost every future stage of the disease; but I cannot speak favourably of any of these applications as early remedies, although they are undoubtedly extremely useful as soon as the acute symptoms are subdued, when the vessels of the eye remain enlarged, and the conjunctiva has a loose relaxed appearance. The early stimulant plan is certainly, to say the least, equivocal practice, and is also very painful and uncertain in its operation, and will occasionally disagree so much, that, by the time you have discovered its injurious tendency, it will be too late to prevent the mischief such a mode of practice has occasioned: you cannot, as Mr. Ware advised, discontinue the use of stimulating applications, and after having bled, purged, and lowered your patient, resume them again; the mistake will be fatal to your patient's vision, for the only opportunity of diminishing the extreme extent of inflammatory action by proper and efficient means, has passed away in the employment of irritating and injurious remedies: as, therefore, you cannot tell beforehand with certainty in which cases these harsh applications will be suitable, and those in which they will disagree, it would be improper to use them at hazard, while you possess, in antiphlogistic means, remedies whose powers have been ascertained, and may be always safely employed and trusted.

When the disease, having been acute, shall have been rendered much milder by the aid of antiphlogistic treatment, or shall have degenerated into a chronic state, or exist only in a very slight degree, it will be necessary to use local astringent and stimulant remedies; such as the zinc wash, or a solution of the nitrate of silver; and it will be adviseable to employ, at this season, some form of counter-irritation, such, for instance, as a blister at the nape of the neck, or behind each of the ears, recommending at the same time an avoidance of all means calculated to aggravate the malady, and particularly any undue exposure of the eyes to the influence of a cold moist atmosphere.

But if suppuration of the eye-ball and sloughing of the cornea have commenced, you must cease your antiphlogistic remedies. The powers of the system will now be fully required, and it will be your duty to support them. The management of suppuration of the eye-ball, and the treatment of sloughing of the cornea, have been so fully discussed in a former lecture, and will constitute such necessary objects of investigation at a future part of the course, that I shall not detain you, on the present occasion, by detailing the various curative means to which you should have recourse.

As to the dietetic part of the treatment there is little to be said: the state of the symptoms and the stage of the disease, conjoined with the patient's mode of living and his habit of body, will be the chief circumstances influencing your judgment as to the extent to which you may deem it prudent to reduce the quantity and lower the quality of his aliment, and also the time at which it may be necessary to increase and improve it. The acute stage will require the lowest scale of diet, somewhat more judiciously selected than ordinary; and the state of suppuration of the globe, and sloughing of the cornea, will frequently demand, always indeed where the vital powers are much depressed, the use of a nutritious and stimulating diet.

In conclusion, I would remind you that, in far the greater number of cases which you will be called upon to treat, the symptoms are so

little severe, that slight attention to the habits and diet of the patient, the administration of a few doses of purging medicine, the use of an astringent lotion, and the application of the ung. plumbi to the tarsal margins in an evening, will comprehend every measure which may be required for their cure.

AN ESSAY ON FEVER.

By Thomas Spence,

Assistant-Surgeon, 52d Regiment.

[Continued from page 384.]

Fevers are occasionally observed to gain insidiously a powerful hold upon the constitution, and are often scarcely suspected before considerable mischief is done: they are much more dangerous than when the symptoms are openly developed. The patient usually, for some time before, feels languid and indisposed, the temper is irritable, and appetite indifferent; the bowels generally relaxed; the tongue foul in the centre, and red at the tip and edges. In this state, very slight causes are sufficient to remove the mask, and fever is excited. Several cases of this description are fresh in my memory; one, however, will be sufficient for the purpose of illustration. A delicate lad was admitted into the hospital for gonorrhœa. He did not at the time make any complaint of general indisposition. A small dose of copaibæ was prescribed, which purged him very violently, and the following morning I was struck with an alarming appearance of listlessness and stupor. He confessed himself to be labouring under pain in the abdomen, which ultimately I found he had been in a less degree long affected with. The pulse was small, quick, and soft; the skin harsh and dry, and the tongue very red. Judging, from these circumstances, that inflammation of the mucous membrane of the small intestines was the pathological cause of the fever, leeches, with the warm-bath and calomel, were employed; but the disease became established of the continued type, the pulse being generally about 120, small and soft; the skin much heated and dry; the tongue red, shining, and parched, with extreme emaciation and debility; the cerebral functions unimpaired. Small doses of calomel and antimony were administered, but could not be persevered with, in consequence of swelling of the tonsils and sore throat. Thus the medical means were reduced to a little castor oil each morning, with strict attention to the general management. The fever, however, continued without the slightest intermission till the twenty-fourth day, when the tongue became moist, the pulse less quick, and he seemed much better; which improvement continued to the 28th, when, on visiting him early in the morning, I perceived great anxiety of countenance, the pulse quick, and the debility much increased. This, at the time, was inexplicable, but, in an hour afterwards, he passed an evacuation consisting entirely of coagulated blood, which was repeated several times in the course of the day, until he lost upwards of three pounds of blood, and was reduced to the lowest extreme of existence. Under this emergency, large doses of opium, with anodyne suppositories, were administered; whereby the involuntary evacuations were checked and sleep induced, from which he always awakened refreshed and disposed to take nourishment. From this period he gradually improved, the recovery only being retarded by collections of matter in various parts of the body. In reviewing this case, we cannot help remarking the extent to which remedial agents were limited: general bleeding was contra-indicated by the constitution of the man, the inflamed state of the alimentary canal precluded the use of emetics, and mercury was necessarily withdrawn in consequence of the swelling of the tonsils and fauces. There was really nothing to be done but to manage the patient generally during the continuation of the fever, to watch for and support him under the operation of the crisis, and then gradually to conduct him through convalescence.

As inflammation of the bowels is seen to render a common fever continued, so inflammation of the mucous membrane of the bronchial tubes renders a continued fever typhus. When it takes place, which it may do, either at the commencement or during the progress of fever, the tongue becomes brown, furred, and dry; the teeth and lips are covered with sordes; the countenance of a livid or sallow colour; the eye glazed, and without expression; the functions of the brain disturbed, the delirium consisting of a low muttering

of incoherent sentences; the vital powers become sunk; the patient lies constantly on his back; the pulse is small, soft, and quick, being seldom less than 120; the skin harsh and dry, and the urine scanty and high coloured; the fæces generally dark. These symptoms being continued some days, are succeeded by a train of circumstances the existence of which renders the prognosis almost hopeless: they are, relaxation of the sphincters, subsultus tendinum, picking of the bed-clothes, and the mucous rattle. This combination of evil symptoms has generally passed under the name of putrid, typhus, low, or jail-fever. They are supposed to invest the disease with extraordinary powers, and render the person labouring under them capable of contaminating others. In this particular, as well as most others, it would be well if medical men would confine themselves to facts which, to speak legally, they know of their own knowledge; then, indeed, we might hope to be rid of the odious establishment yeleped Quarantine; then would a serious interruption to our trade be removed, and a considerable expense to the public saved; but what is of more consequence still, we should no longer hear of the mother deserting her sucking child, nor of the infected being turned into a pig-stye, or allowed to die by the road-side. This is no over-drawn picture of the evils resulting from a belief in the doctrine of contagion; instances too many have occurred in this country (Ireland) within these few months. Adhering to the principle of speaking only from personal observation, I can most confidently state that I have never seen fever propagate itself by contagion. I can conceive that if an individual be confined to bed in a close room, where there is no ventilation, without strict cleanliness, let him be labouring under whatever disease he may, such a state of malaria will be produced that his symptoms will assume this particular character, and any person who may be long exposed thereto shall in like manner be infected. This would never be the case, I am convinced, where cleanliness and ventilation were maintained; neither have persons on being moved from the infection been found to propagate the distemper, so far as I have observed.

The treatment of this stage of fever is very simple, and being conducted upon principles having reference both to physiology and pathology, will be successful in a large majority of cases. As this most commonly supervenes upon the type which has been previously described, it will here only be necessary to allude to the specific condition under consideration: in addition to other local derangement we have a mechanical obstruction to the action of the atmospheric air upon the blood in the lungs, and consequently a quantity of carbon is retained in the circulation. The measures are evident, and the most important is to encourage or promote expectoration, whereby the glutinous secretion forming the impediment is removed. For this purpose a combination of ipecacuanha and squills, in doses of two or three grains each, may be administered every three or four hours. If the patient cough pretty strongly, it may be considered a very favourable symptom, as it assists powerfully in relieving the air-passages. A blister to the throat or nape of the neck is generally of service. A free circulation of pure air cannot be too strongly insisted upon, the surface of the body at the same time being preserved from cold. Small doses of calomel and castor oil should be given occasionally, for the purpose of gently acting upon the primæ viæ. A warm bath has often a very beneficial influence; it tranquillizes and produces sleep. Should the exhaustion be too great for this measure, the body should be sponged frequently in the day with tepid water and vinegar. The head should invariably be shaved, and kept cool by cloths dipped in an evaporating fluid: the thirst may be allayed by acidulated drinks, or by saline effervescing draughts. Stimuli I look upon as worse than useless: they always fail to give strength, and increase the inflammatory action: to a mild unirritating diet, however, there is no objection, and good jelly or broth may be given with advantage. It is in this stage of fever that an intelligent and careful nurse is invaluable, as the patient requires incessant watching and the most delicate care. Bleeding from the arm I have generally avoided after these symptoms have manifested themselves, but frequently with benefit have applied leeches to the head or seat of pain.

The typhoid form of fever has, within my observation, very frequently become remittent; when the tongue, instead of being constantly dry and

brown, is, at certain periods, perfectly moist; the skin covered by profuse perspiration, the delirium ceases, and the patient is apyrectic. This remission, however, is of short duration, for soon the fiend resumes his power; again the mouth is parched, the skin dry and hot, and the delirium returns. To explain the cause of this change, is, I confess, far beyond my capacity; but, to illustrate the position, I will relate a case which occurred to me a little time ago. A soldier, who had been indisposed for some time, was admitted into the hospital with continued fever, in which very considerable inflammation of the mucous membrane of the small intestines was manifest. He was treated generally according to the principles here described, but the progress of the disease was uninterrupted, and the bronchial affection having set in, typhoid symptoms became established, until the night of the seventh day, when, visiting him about twelve o'clock, I found him in a complete state of collapse, no pulse at the wrist, the extremities cold, and he had passed a copious evacuation involuntarily. By the immediate administration of stimuli, with the application of heated bottles to the extremities, he rallied a little; the pulse returned in the right arm, and he became tolerably sensible. I then gave him five grains of the sulphate of quinine and eight of the carbonate of ammonia, which produced considerable reaction, attended with a state of tranquillity and succeeded by profuse perspiration. This encouraged me to repeat the medicine, and during the day he seemed much better, but had an exacerbation of fever from seven o'clock till ten, which was followed again by perspirations; the stools were still passed involuntarily, and the exhaustion was very considerable; the tongue, except during the remissions (which occurred regularly twice a day), was black and dry. At last, the voice having become weak and almost inarticulate, the eyes glazed, and the delirium constant, on the eleventh day, exhausted, he expired. The examination of the body exhibited appearances corroborative of what I have before asserted; the mucous coat of the ileum being highly injected with several ulcerations, and the inner surface of the trachea and bronchæ changed from a white to nearly a black colour.

[To be continued.]

SELF-SUPPORTING DISPENSARIES.

To the Editor of the Medical Gazette.

Southam, Warwickshire, Nov, 18, 1832.

SIR,

WHOEVER may have been the author of the leading article in the Medical Gazette for September 22. on self-supporting, charitable, and parochial dispensaries, deserves my acknowledgements, and I beg to make them to him through you.

I must confess I have long thought the medical press tardy in their notice of my plan, as well as of the principles I have so long advocated; and which, at no inconsiderable sacrifice of time and money, I have endeavoured to bring into practice.

I have lately been requested by some of the governors of two County Hospitals to aid them in a code of laws which should combine the self-supporting dispensary with the present hospital system.

The inclosed letter has been the result: the matters to which it relates so nearly concern the honour and interests of the medical profession, that I thought it proper to submit it to them for examination, before I finally conclude on sending it to the Council, for whom it is ultimately intended: perhaps your pages are well calculated for such a purpose.

I expect that a desirable medical reform will soon follow from the general adoption of my plan. Hospitals will cease to be so exclusively the road to profitable and monopolizing practice as they have hitherto been. The junior members of the profession will procure much practical knowledge, and some profitable reward, when they first begin the world, and not have to purchase a parish practice, or canvass for permission to work hard at an honorary dispensary for nothing, as they have hitherto done.

Farming the sick poor of parishes will be discontinued; the aggregate of parish payments, and the subscription from the free members' fund, will afford a higher rate of payment than can ever be obtained from the same sources, by jobbing with overseers for parishes, or writing bills for day labourers, however familiarly and ingeniously the "craft

may be followed," and protected by the "custom of the trade."

There are many other advantages likely to attend the more general and complete application of the system—both to the science, and payment of time and knowledge in the profession. The retail druggist may complain, but the physicians, surgeons, and apothecaries, will be rewarded better by the higher classes of society when they have changed the present false and unskilful position in which they now stand to the lower classes.

Nearly thirty years ago, Mr. Editor, there was a discussion in the Gentleman's Magazine on the best mode of forming a circulating country library. It appeared every town wanted a library, but few knew how to set about forming one. Rules were soon supplied, and the rising generation appear intuitively to have caught a knowledge of the advantages and disadvantages of each particular plan, for the best are not without some inconveniences. Now cannot something be done in the same good humoured way with regard to the constitution of dispensaries? I think so, and shall be truly happy if I have been in any way a useful pioneer in amending so important a part of the machinery of common life.

I have the honour to remain, sir,
Your humble servant,
H. L. Smith.

On the Constitution of Infirmaries.

My Lords and Gentlemen,—I have for many years paid considerable attention to the formation of infirmaries, as well as to the history and causes of poverty amongst the labouring classes, as they have for upwards of twenty years unfolded themselves in this neighbourhood, particularly in connexion with that subject which to a surgeon may be considered a natural, fair, and appropriate field of inquiry, viz. their provision for sickness, and the ultimate effect which our public charities, and parochial arrangements, produce on their feelings and conduct. On hearing, therefore, that you are about to revise the laws and regulations of the ——— Infirmary, I am induced, with the greatest respect, to submit to your consideration the following not unseasonable observations.

The cause of suffering humanity amongst the poor in every shape is one of great interest and importance to those whose wealth, rank, and influence enable them to exercise a portion of the *governing power*. It is the admitted duty of all, who have leisure for thought and deliberation, to exercise these faculties as talents for the benefit of others who have not time to think and contrive for themselves.

In the establishment of clothing societies, the allotment of garden ground to cottagers, and the admirable application of life annuity calculations to clubs, the resident gentry of this country have in many places within the last few years manifested a sincere and commendable desire to improve their condition, and, consequently, to elevate the character of the working people in their respective parishes, to redeem them from extreme wretchedness, and from practical slavery, by enabling them to work more for themselves, and less by the round.

Still much remains to be done, in mere justice, as a return for the enjoyments we derive from their labour, and very much, indeed, before the divine principles of christianity can be said to be duly acted upon even in Great Britain.

The supply of food and raiment, fuel, and lodging, which the cottage-garden system, in conjunction with clothing societies, shoe, and coal clubs afford—though of the first necessity, is not all that is comprehended in the command for providing "for our own household," a command which, to neglect, is said on the highest authority, to evince conduct worse than that of the infidel. Nursing, and protection from a ruinous expense in sickness, and an income for maintenance—both then, and in old age, are necessary for those who look forward to partake of the common lot; and it would buoy up to generosity a manly spirit in health, and allay the feverish anxiety of sickness, were a better system introduced for attending the working people generally at such distressing times, *at their own homes;* their hearts are then opened, and social unions, on the principles of life-annuities, would become more popular: they would be trained for them, and would understand how a small monthly contribution could secure an income for declining years. How hard it is that industrious honest men in

their old age should be driven out to work in the cold and wet, because four or five comparatively rich persons in a parish cannot be found to take the management of such institutions. No man who insures his life, or his house from fire, can be ignorant of the power of many to do that for one which he cannot do for himself.

Such societies, such systems, are necessary before the working classes can find the way which tends to a state of independence; a safe, progressive, rational, and I hope some time national mode, of emancipating themselves from the feudal spirit of our parish law.

They are now constrained, however large their gardens, decent their clothing, and deeply stamped with English liberty their hearts may be, to form an alliance, and to renew, on every trivial case of sickness in their families, their connexion with the overseer, through the parish doctor; and *if it is really desirable* to recover them from their mean state of dependence, and wean them from their accustomed patrimony—parish pay and the workhouse—privileges which, in their simplicity, they mistake for blessings; if we are to do by them in this particular as we would be done by, and as we do by our own children, we should not stop when we had taught them to read and write, but endeavour to make them provident and reflecting beings. The means that invite attention to these matters deserve consideration, for it becomes education for the people in its best practical sense.

Institutions, then, must be generally established that shall address themselves to all the feelings and affections of their nature—institutions that shall more immediately tend to advance their interests, supply their wants, and insure them more kind attention than paupers can receive from their parish—than a slave can expect from a rack-renter, who, instead of purchasing him as an African for 60 or 80*l.* would give as much to be rid of him.

Large bodies are at all times moved with difficulty from their first position; and it is only when important changes in the laws of public charities are contemplated, that the governors, and other influential persons, can entertain principles which, however sound, moral, and religious, may require an admission of past error, and involve new combinations — principles which shew that charity is something more than almsgiving, or ticket-begging, and that as evidenced in many of its present most popular forms, it does more harm than good; and yet these admissions must be made, and our present mode of assisting the poor changed for their own sakes, or the charitable will give until they have nothing left to give, and all will become confounded by the progress of the monster, pauperism, (with its attendant evils —improvidence and profligacy) which we invite, foster, and feed, instead of strangling in his birth.

It will presently appear, that, by means of a differently constituted provincial hospital, acting in union with a comprehensive dispensary system, which shall effectively and affectionately embrace the working population of districts of parishes, that principle of combination peculiar to our nature as social beings, now too frequently an abused power, will be directed to its proper objects throughout the whole country, and union will cease to be applied to those purposes which may prove injurious, as combinations against masters have hitherto been, without being of real use to the parties combining.

Hundreds of thousands of intelligent labourers and mechanics have, for many years, been made the tools of crafty and designing publicans and agitators; who will be dislocated from their position, profits, and honours, when the social principles of Christianity are thoroughly acted upon in the country, and when all that is noble, generous, and good, will be concentrated in a system of social harmony, to promote the interests of the industrious many who would fain enlist themselves under other rulers than those who assume to govern, but, in truth, tyrannize over them.

How many young persons are daily sent into the world, trained by our infant national or dissenting schools, with excellent natural dispositions—industrious, humble, kind, virtuous — the bright promise of England's future strength—who, through the combined influence of contact with a debased and profligate neighbourhood, and the want of notice and encouragement from their superiors, in some thoughtless moment of youthful folly lose their character before they can rightly estimate its value, and confined, by its loss and the poor-laws, to one parish, have sunk

down in the end to be the burden and nuisance of society.

Hospitals and dispensaries may be made to draw a line of separation between the comparatively provident and improvident; and whilst they provide better attendance for the most abandoned, they may extend their healing influence to the cottage as easily as to the ward of the hospital, and permanently unite the physical strength with the moral worth of each neighbourhood. To carry these views into practice, it appears to me that the in-patient department of your and every other infirmary and hospital, should for the future be separated from the out-patient department; and the latter divided and extended throughout the country, or only bounded in its operations by invading the province of another hospital and its tributary dispensaries.

The patients to the hospital should be more frequently sent by the dispensary surgeons; by which means, an hospital will secure such occult, difficult, and protracted cases, as well as those requiring surgical operations, that are now to be found neglected in every part of the kingdom. It is notorious that many hospitals are half filled with patients sent by parish officers, or well-meaning governors; which patients are not proper objects of admission—or not so much so as others who are excluded: invariable discrimination in the recommendation of patients cannot be expected by gentlemen out of the profession.

There should be a separation in the wards of the hospital: the class of free subscribers to the dispensary (even in the hospital) should be separated from the parish paupers. The colouring of the walls of the ward would form nearly all the positive distinction in the treatment of the patients.

Every market-town and village in the county, having two or three medical men, and a district of country containing eight or ten thousand inhabitants (the more the better), and four or five persons to constitute a local or branch committee, in connexion with the hospital committee, should forthwith establish a self-supporting charitable and parochial dispensary.

The funds for its support are derived from the very small weekly contributions of industrious labourers—from charitable subscriptions, and parish payments in proportion to their population, being the sums they now pay to medical men for "farming their poor;" which jobbing it would for the future do away with.

For the details of such institutions, and the good they have done, however imperfectly they have been permitted to be established, I must respectfully refer to the Reports from Coventry, Birmingham, Derby, Burton, Wellesborne, &c.

Every ten thousand inhabitants would be able to maintain a self-supporting charitable and parochial dispensary; and each of the provincial and county hospitals in the kingdom would have tributary to them from thirty to fifty dispensaries. If each of these dispensaries subscribed for four or six in-patients per annum, there would be a compensation made for the source of income they now derive from parish subscriptions, and which, in some cases, would be discontinued.

The secretary's accounts for every self-supporting charitable and parochial dispensary ought to be settled monthly, or at least quarterly. The medical reports, containing the population of the district embraced by the dispensary—the number of free, charitable, and parochial members respectively applying for relief—the diseases of each class—the age, sex, &c.—with a meteorological journal, should be presented monthly to the hospital, and transmitted, when embodied, to the Secretary of State's office, to a Central Board of Health, or to a council appointed by the Colleges of Physicians and Surgeons in London. These aggregate reports would, in a short time, become valuable materials for statistical tables and information: the actuaries at public offices require such data.

There are many other suggestions and arrangements that would follow from bringing something like a system or method into practice throughout the country, where, from the want of it, the experience and practical knowledge of ages is continually superseded by some ingenious theory or another. An epitome of the history of medical science, from the time it deserved that name to the present time, will be found in the history of cholera since its introduction into this country; from the certain specific remedy, the oleum cajeputi, of which we now hear nothing,

to the single drop of spirits of camphor, transfusion, or gallons of cold water, of which we hear so much.

Regularly digested statistical reports would become general. They can only be given by an institution such as I recommend. A certain proportion of the whole population, sick or well, would be always before the medical officers—perhaps one-half, including the free members and paupers. The public require this information; the government would be enabled to exercise with more discretion their paternal duties in cases of extraordinary fluctuations as to food, work, or the public health. The profession would be more recognized and more trusted to by the governing powers; representation in the legislature would probably follow; and a long life of useful public service would not be (as it has hitherto been) neglected, unknown, or dishonoured, in the medical profession more than any other.

* * * * * *

I have the honour to remain,
My Lords and Gentlemen,
Your obedient humble servant,
H. L. Smith.

PHLEGMASIA DOLENS.

To the Editor of the Medical Gazette.

Sir,

Should you consider the accompanying case of phlegmasia dolens, successfully treated by mercury, of any importance, I will thank you to give it a place in your useful journal.

The researches of Drs. Davis and Lee, and MM. Bouillaud and Velpeau, have shewn that phlebitis, if not the cause, is often the associate of phlegmasia dolens.

The now well-known effects of mercury, in arresting and controlling the morbid action of the capillary vessels, led me to believe that the judicious employment of that medicine might possibly prove as strikingly remedial in phlebitis as in other inflammatory affections. I therefore determined to embrace the earliest opportunity of putting this opinion to the test of experience. The following case is the result of the first trial of the remedy; and, as far as an isolated example can support any particular mode of treatment, it appears likely to become eminently beneficial. Though the case here narrated was certainly a severe specimen of the disease, it was cured in a third of the usual time; and as no other means, either general or local, were had recourse to, there can be no error in ascribing the benefit obtained to the mercurial action.—I remain, sir,

Your obedient servant,
Thos. Slater,
F.L.S. M.R.C.S. &c.

Poole, Dec. 14, 1832.

Mrs. Maybee, a pale delicate woman, 22 years of age, was delivered, on Thursday, the 18th of April, of twins, being her first confinement. Two days after her labour, she complained of pain at the back and upper part of the left hip, and also in the groin, with tenderness of those parts. On the 21st, great pain was experienced in the calf of the leg. The pain now (May 4th) extends to the ankle, with generally increased sensibility on pressure of the whole limb, and tenderness in a marked degree in the groin and in the course of the femoral vessels; that part of the thigh below the point at which the vessels perforate the tendon of the triceps is less tender; in the ham the soreness is very considerable. The inguinal glands do not appear to be enlarged. The entire extremity is of the usual characteristic whiteness, hotter than natural, and œdematous, especially about the foot; there is also great muscular debility. The pain has been so violent that the patient has had but little sleep for many nights previous to the last, when, by the use of an opiate, some rest was procured. Pulse 120; tongue moderately clean. The lochial discharge is less than usual. The milk is secreted sparingly. The bowels being constipated, some castor-oil was directed, and afterwards five grains of the blue pill, with a quarter of a grain of opium, were ordered to be taken every four hours.

May 8th.—The swelling, both of the thigh and ham, is considerably diminished, but below the knee it remains much the same. The tenderness is not so great, and the limb is moved with less suffering. Gums slightly sore.

Continue the pills.

10th.—Since the last report the disease has attacked the other leg, but in a mild form. The swelling in the left

leg does not now extend above the knee, and there is but little tenderness in the course of the femoral vessels. The mouth remains sore.

15th.—The right leg and thigh have been a good deal swollen, but the pain and tenderness much less than were experienced at any time in the left. The patient can move freely in bed, and without much uneasiness.

18th.—The complaint in the limb last attacked is rapidly giving way; there is now but little swelling above the knee, or soreness in the course of the vessels. There has been no enlargement of the lymphatic glands on either side. The patient complains of her mouth, which has been kept tender by the continued use of the pills.

22d.—No vestige of the disease remains in the left lower extremity (the one first attacked); the right is slightly swollen about the foot and ankle, but quite free from pain. The patient is stronger and feels better than could have been expected after so severe a disease.

ANALYSES & NOTICES OF BOOKS.

" L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

Dr. Hope's Morbid Anatomy. Part I. *Diseases of the Respiratory Apparatus.* 1833.

It is a great mistake—as it appears to us—to assert, as many constantly do, that morbid anatomy does not meet with its due share of attention in this country. Not a year passes in which some contributions to this branch of knowledge are not presented to the public; and the splendid works of Hooper and Bright, and Sir A. Cooper, which have issued from the press at no distant period, are not less honourable to science than creditable to the arts. Morbid anatomy, indeed, is regarded in the present day as of paramount importance, and our apprehension with regard to the rising generation of practitioners is, lest they be led to attach too much, rather than too little weight to it; lest, in dwelling upon its excellence, they limit their view to its contemplation, forgetting that though extremely useful to recognize in the living, and describe, paint, and preserve from the dead, the various organic changes to which the body is subject, it is yet more satisfactory to the patient, and creditable to the practitioner, to know how to relieve suffering, arrest decay, and prevent those changes from occurring which, when present, the morbid anatomist is much more frequently able to indicate than to cure. The more intimately acquainted any one is with morbid anatomy, *cæteris paribus*, the more likely is he to direct his practice to a rational end; but the condition (namely, that he be in other things alike) is to be kept in remembrance; and if he has devoted his mind with too engrossing a study to the investigation of changes of structure, then the probability is, that though in organic diseases he may be more skilful in diagnosis, and though the indications which he attempts to fulfil may in such cases be more in conformity with the actual condition of his patient, yet in affording relief in the majority of complaints, will he be far behind him who is merely an attentive and judicious observer of symptoms, and of the effects of remedies. Those acquainted with the profession in London could have had no difficulty ten years ago in fixing upon two great rivals; one of whom founded his reputation on the basis of anatomy, in which, more especially as connected with disease, he took the lead over all his contemporaries: his skill in detecting disease was not less remarkable than the felicitous manner in which he conveyed to the mind of the patient or his friends a satisfactory idea upon the subject, and a conviction that they were in the hands of one who thoroughly understood their complaint. The other trusted less to pathological minutiæ, and more to the skill which results from a constant observance of the connexion between symptoms and remedies, studying the body and the mind of his patient, as influenced in their functions by disease, and as controlled by external agents; and thus acquiring a knowledge, less curious, it may be, as to the morbid changes which disease produces, but far more extensive as to the power and adaptation of remedies; commanding the confidence of his patients on a principle which comes home to all—the art of affording them relief. We do not mean to say that the former was deficient in his power of fulfilling indications, nor that the latter is defective in

a knowledge of morbid anatomy, but we have chosen the parallel as illustrating two distinct modes of contemplating disease, as adopted by eminent men of our own times, each conspicuously successful in his professional career.

From this digression we turn to Dr. Hope's *brochure*, and we apply our remarks in this way: as a knowledge of morbid anatomy is necessary to the accomplished practitioner, and as the time heretofore unavoidably spent in its acquisition is apt to interfere too much with other departments of even greater importance, so every work which tends to lessen the time and labour of the study must be useful, and more useful the easier it is of access. The great objection to most of such undertakings is, that they are either too expensive to be within general reach, or so badly executed as to be dear at any price. The plates before us certainly do not at all equal some of the former class which we could name, neither do they come in any degree within the description of the latter. They correspond in size to the "Cyclopædia of Practical Medicine," to which the work would seem to be intended as a kind of companion, and a very useful companion it is likely to prove. The delineations are accompanied by letter-press, containing succinct descriptions of the morbid appearances represented, and having references to the work of Andral. In expressing our opinion thus favourably to the undertaking, we must take leave to point out what we think imperfections in the plates, and which might easily be remedied in those which are to come. In the first place the colouring is too high; and although this objection will be lessened by the fading which will no doubt occur, still it is not the less conspicuous at present. There is a brightness about them with which the eye is not familiar even in recent parts, and which it therefore feels to be exaggerated. Again, we think too many figures are introduced in each plate: this dazzles and distracts, gives them a patchy appearance, and takes rather from the effect; and, not to multiply our criticisms, we disapprove very much of cutting portions of diseased organs into squares, and other regular shapes; it gives them too much the appearance of specimens of minerals—of variegated marbles, for example. Had the work been completed, we should have expressed ourselves less strongly on these little imperfections, because it would then have been too late to expect the improvement of any defect; and we should have dwelt more upon what really deserves praise, viz. the clearness of the delineations, the great care evidently taken to make them accurate, the perspicuity of the descriptions, and the moderation of the price, all of which are good, and we trust need not the spur of criticism to cause their being continued; but they will appear to still more advantage with the few amendments we have ventured to suggest.

MEDICAL GAZETTE.

Saturday, December 29, 1832.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

A CONFIDENTIAL COMMUNICATION.

"Shall we *now* learn who is in reality the mean fabricator of the MOCK LANCET,—the lying and infamous emanation of the BATS? Yes, we shall discover and trace the base reptile through all his secret, subterranean, winding recesses. Ay! we repeat; the creature shall be dragged forth and crushed, for our heel is already on the serpent's head."—*Lancet, Dec.* 22, 1832.

THERE cannot be a greater compliment to any anonymous writer than the manifestation of an intense curiosity to know who he is: we therefore feel greatly flattered by the extreme anxiety displayed by our much-respected contemporary, in an article from which the above is a short quotation, to discover the author of our original prospectus, as well as of several other papers which have appeared in this journal. That he should not yet have forgotten the sketch of his moral qualifications which appeared above five years ago, is a pretty satisfactory proof of the fidelity of the likeness, and of the power to aim his thrusts at the most vulnerable parts, possessed by the "mean, cowardly, dark, malignant, secret, literary assassin," (as our facetious friend entitles him,) by whom they were inflicted. Our worthy

fellow-labourer in the paths of science adopts the old expedient of naming one suspected person, in hopes, we presume, that he will either plead guilty or not guilty to the moral murder of the innocent and interesting victim; but as the gentleman alluded to seems disposed now, as we believe on former occasions, to be contumacious, and as we, on the contrary, are the best-natured and most communicative persons in the world, and as, besides, these holiday times are ill suited for regular business, we have a great mind to set graver matters aside, for the pleasure of telling our contemporary — confidentially, of course —*who* really does write our leading articles; who it is that has the audacity to bandy words with the Lancet's spoilt child and his immaculate patron. Now if he will but promise his constituents—we beg his pardon—his readers, to make no dishonest use of our confidence, we may hereafter be induced to speak more plainly; but till we have a "pledge," (which of course he is ready to tender) we must confine ourselves to a few brief sentences—true, indeed, but dark and mysterious—lest those with whom we are not on the same friendly terms should also penetrate our mystery. Be it known, then, that the effusions which have so nearly driven our contemporary into phrenzy, were written—by no one: no man—"nor woman neither" — can claim them as their own; and although we doubt whether, as above surmised, any of them belong to the "serpent" tribe, yet it is pretty clear that the "creatures" can sting. The expressions—all but maniacal expressions—of hatred, such as are used towards his supposed tormentors, are never wrung from any, but by suffering which amounts to torture: they come from the heart—the very heart, and are involuntary tributes to our power: they are the agonies of a demented outcast, levelled with the dust by the mere force of opinion, and so sensitive and sore at every point of his *morale*, that we can at at any time set him all on fire, and fret him into madness by a word. We will further declare, for his gratification, that on no two occasions, when he has been goaded to more than usual ferocity, has the blow come from the same hand: some are living, and some are dead—some we do know, and some we never did know—to whom the merit is due of having aimed the shafts which have sunk so deep, and which have rankled so long. In a word—to put our amiable antagonist out of suspense, and make a full and free confession—our leading articles, whether touching himself or the several protegés whom he names, were all written by US.—— There, now, most potent conjuror, whose music is to charm us from our hiding place, canst thou read us our riddle? Of course thou canst; for as Hamlet says, "'tis as easy as lying."

As to the learned Professor of Medicine in the University of London — alas! that he should have compelled us to associate him with such a companion—has he no friend candid enough to open his eyes, and to tell him what his professional brethren really think—and, in his absence at least, freely say—on the subject of his discussion with this journal? Does he imagine that sending communications aimed at us every week to the Lancet, will be received as a proof of the indifference which he affects? He entered upon a discussion regarding medical education, and abandoned it when he found himself worsted: he attacked all the schools in England indiscriminately, endeavouring to bolster up his own at their expense;—we defended them, and routed their assailant at every point. Does he conceive that the public can be induced to forget this, because he now chooses to start a fresh subject? We have no desire to triumph over his discomfiture, nor should we taunt him by keeping the subject

alive, if he had himself the common discretion to let it rest. But so long as he endeavours to throw dust in the eyes of the profession, by interminable letters in the Lancet, as to the degree and manner in which his colleagues expressed their dissent from his doctrines—as if that had been the subject of the discussion—so long shall we repeat that this attempt is a mere *diversion*, to cover his retreat;—yet even on this ground, if he can wring from his colleagues any expression of approbation, however cold, regarding those points of his original lecture or subsequent conduct which we have censured, we faithfully promise to transfer it from the pages of his journal into our own. *Till then we have done with him and his letters.*

CONVERSAZIONE MEETINGS AT THE LONDON UNIVERSITY.

Dr. Macleod has forwarded to us the following letter from the Dean of the Medical Faculty in the London University, with a request that we should publish it, and adding, "that it was but the week before last that the Professors did him the honour to send him a card of invitation for the present season." Of course we can have no hesitation in complying with his desire, although we think he has taken very unnecessary trouble in writing to the Dean of the Faculty at all, and although it be against a general rule of ours to insert letters contradicting the falsehoods of the Lancet: in fact, we never could afford space to do so.

Dr. Thomson's Letter.

3, Hinde-Street, 26th Dec. 1832.

Sir,

In reply to your note requesting to be informed whether your name be erased from the list of visitors to the evening conversazioni in the University, I have to inform you, that on examining the list, I find no such erasure: your name remains in the list in the place it has occupied for the two last sessions, and to my knowledge no such erasure has ever been contemplated.

I have the honour to remain,
Your obedient humble servant,
Anthony Todd Thomson.

To Dr. Macleod.

THE LATE MR. HENTHORN.

(From a Correspondent.)

We have received intelligence of the death of the oldest, and one of the most respectable of the members of the surgical profession in Ireland—James Henthorn, Esq. It occurred at his residence in Stephen's Green, Dublin, on the 18th instant, occasioned by a fall in attempting to go up stairs without assistance.

In point of age (we understand he was about 90), Mr. H. might have been styled the father of his profession; but he merited the appellation in a more honourable sense. He was the originator of that institution which has raised the profession in Ireland to its present highly respectable position: to him, in conjunction with the elder Mr. Dease, and the present able director-general of military hospitals in Ireland, are to be attributed the foundation and erection of the Royal College of Surgeons in that country. But Mr. Henthorn's labours, connected with this establishment, did not cease with its foundation: on him devolved the arduous and responsible task of watching over, and directing the progress of its superstructure, and the value of his services as secretary (we should add that they were wholly gratuitous) was duly appreciated by the members of the college, who, in testimony of their respect and approbation, voted him a piece of plate on two different occasions.

Mr. Henthorn was the main instrument of appropriating the resources of one of the most extensive institutions in the empire to the purposes of medical education. The House of Industry of Dublin contains within its walls a population of nearly 2000 souls of all ages, exhibiting every grade and variety of chronic disease, both mental and bodily. To his exertions, when a governor of that establishment, the medical profession is indebted for the erection of the extensive medical, surgical, and fever hospitals, now connected with it, where so many of the present and rising generation of medical men have received their first rudiments, and which have contributed a large proportion of those valuable pathological and surgical observations

with which the Dublin periodicals have from time to time supplied us. Mr. H. was for a long period surgeon to the Police establishment and to the Lock Hospital of Dublin, in the latter of which he was distinguished for his judgment and discrimination in the treatment of syphilitic complaints. The recent revolution in this branch of practice had been to a considerable extent anticipated by him—a fact which should have received an early publicity, had his instructions been acknowledged in certain quarters with becoming candour*.

To a manly and graceful deportment, were united in Mr. Henthorn the more enviable qualities of a mind well furnished from the varied stores of literature: his mild and agreeable manners, and rich fund of conversation and anecdote, rendered him a delightful companion, and being peculiarly exempted from those foibles which are conspicuous in most old persons, his society was pleasing till almost his latest hour. A gratifying tribute was long since paid to the kindly feelings of his heart in the subjoined lines:—

> His human kindness equal succour lends
> To those whom heaven abandons and befriends†.

BOTANICAL PRIZES, APOTHECARIES' HALL.

(From a Correspondent.)

The gold and silver medals annually offered by the Society of Apothecaries to all students (not being apprenticed to members of the Society) were on Tuesday, the 4th instant, awarded to Mr. T. H. Cooper, of the London University, and Mr. P. K. Weston, of King's College.

As these prizes are given, not merely for comparative, but for absolute merit and positive proficiency, (last year only one medal was decreed, the other being withheld) it is highly creditable to these young men, and gratifying to their friends, to have such evidence of the right employment of their time, and to be thus honourably distinguished as the two best botanists that the metropolitan scho ls this year afford.

Long before the examination took place, we heard that Messrs. Cooper and Weston were the favourite candidates; and from the former gentleman being a student of several years standing, and the latter of one year only, it was generally expected that the prizes would be awarded as they have been. We therefore think it unwise, and we are sure it must be contrary to his wishes, that the success of the gold medallist should be mentioned, by his would-be friends, as a triumph over his fellow candidate, to whom the silver medal was decreed. At any time we should have thought such reports ungenerous; under present circumstances we think the exultation foolish; for although the success of the senior student is highly honourable, it can scarcely be regarded as a triumph over a competitor so much his junior; and our veracious contemporary, when affirming that this was "the first examination at which the King's College students have attempted to contest the gold medal with those of the London University," would have done well to have recollected that the College was only opened in October 1831, so that it was the very first opportunity of competition which has occurred.

* For an abstract of Mr. Henthorn's practice in these affections, see the Dublin Hospital Reports. Vol. II. pp. 188-9.

† The Metropolis, a poem, Dublin, 1805.

CLINICAL LECTURE ON DISEASES OF THE URETHRA AND NECK OF THE BLADDER,

Delivered at Middlesex Hospital, Dec. 22, 1832,

By Sir Charles Bell.

Gentlemen,—Former habits continue to influence me; and if I have promised a lecture, and am not able to deliver it, I feel as if some important duty were neglected; indeed I have always found that what was promised to the students was exacted to the letter. You know that I have been absent from the wards in consequence of being a little unwell; happily, I can get the business there carefully done for me, but I cannot as yet have my duty performed here; I have therefore made a little exertion to be with you.

I stated, at the last lecture, that there were nine cases of diseases of the urethra and neck of the bladder to which I was desirous to direct your attention. We were about to have read to us the third case, and, in order to bring us to due reflection on the subject, I will request that it be now done.

Case III.—*Stricture of the Urethra, with Fistula in Perineo, following the Operation of piercing the Stricture.*

Patrick Shannon was admitted September 11th, having fistula in perineo, with difficulty of passing his urine. His whole appearance indicates long continued suffering, and he gives the following history

of his complaint. As far back as 22 years ago he was seized with retention of urine, for which an instrument had to be introduced. Three years after this, he underwent a course of treatment by the bougie for a very narrow stricture, and was cured. He remained free from any complaint till three years ago, when he was again attacked with a difficulty of voiding his urine. This progressively got worse. He was obliged to leave his situation as groom in a family, and he applied for relief at a neighbouring dispensary. At this time, he states that he could scarcely pass a drop of water. Upon his being admitted into the dispensary, the surgeon introduced an instrument into the urethra, which had an apparatus within it for cutting through the stricture, and, to use the patient's expression, upon "shooting this," the instrument was admitted into the bladder, and the urine drawn off. A bougie was subsequently introduced regularly into the urethra, and he felt completely relieved, passing his water with perfect freedom. Three weeks from the time of the operation, he observed a small swelling commencing in the perineum, at the place where the stricture had been situated. This gave him great pain, and, in process of time, it burst. He soon found that the urine, when discharging it, came partly by this abscess and partly by the natural passage. From this time various other abscesses formed in the perineum, from all of which the urine dribbled.

Upon examining the urethra, he is found to have a stricture situated near the bulb, through which it is impossible to pass the smallest sized bougie or catheter. The perineum is knotted, irregular, and undermined with fistulous openings, fungous growths, and sinuses; these extend even as far back as to the tuberosity of the ischium. At various periods since his admission into the hospital attempts have been made to introduce an instrument into the stricture, with the view of dilating it; but these have proved unsuccessful, and they have been followed by severe attacks of shivering and fever, which made it necessary to desist from them. At present he makes his water with considerable freedom, and it comes partly from the natural passage and partly from the numerous sinuses in the perineum. He is awakened at night every two hours, owing to the urgency of the desire to make his water.

The most remarkable circumstance in this case, Gentlemen, is the cutting of the stricture by an instrument introduced into the urethra; an operation which is very naturally suggested. It has been thought of by many, and, in criticising it, I in fact bring my later experience against myself, because I attempted it in early practice. I had a flat female catheter made, with a small semilunar slit in the point of it, through which I introduced a lancet adapted to the slit. I forced this catheter against the stricture, and then, by introducing the lancet, cut the stricture.

I had reasons for laying aside the operation; and they are exactly those which I shall cite in criticism of the present case. The principal danger, then, is that of extravasation of urine. It is very difficult indeed to strike the stricture exactly, so as to cut it and cut nothing else. No doubt it would be a happy circumstance if you did just strike the callous stricture, and not touch the membrane; but see how difficult it is to introduce the point of a bougie into a narrow stricture. When you reflect on this, you will perceive that it must indeed be a very nice thing to hit the stricture with a cutting point. Now, if you do not enter the stricture exactly, you open a passage into the spongy body of the urethra, or into the cellular membrane, and let the urine into these textures. Remember that extravasation of urine, although you might say that it is a natural fluid, is so far from being harmless, that it deadens the cellular membrane, causes sloughing, and, at all events, inflammation and suppuration. The first danger, then, is that of extravasation of urine; the second is that which you have seen to happen in the case just read, the formation of abscess. The dripping of the urine into the abscess follows, and ultimately fistula in perineo. The third misfortune to be apprehended is that of making a false passage; for, when you have cut the stricture, it is exceedingly difficult indeed to ascertain whether you are passing your catheter through the stricture which you have partially divided, or whether you are passing it in the manner I described in the last lecture, between the bladder and the rectum.

Now, these are three reasons against the operation. I would further say that it is an easy thing to state what is the rule of the profession generally, but a very difficult thing to say what a very careful, very dexterous, very ingenious, and very safe man, may think himself at liberty to do. I am, however, quite certain of this; that if the leading men in the profession were to say to you and to the practising surgeons in town and country, cut the stricture from within whenever you have a difficulty, incalculable mischief would ensue: how far an individual may raise himself above authority, it is not for me to say; but I am sure, as a general rule of the profession, there cannot be one more pregnant with danger than this of perforating the stricture with a sharp instrument.

CASE IV.—*Stricture of the Urethra with Prolapsus Ani, in which the Stricture had been divided from within.*

For several weeks a patient, J. Hinkley, lay in the bed opposite to Shannon, having suffered the same operation of piercing the stricture of the urethra. He stated, that he had been subject to stricture for four years. Two years ago he applied at the same dispensary in which Shannon had been admitted, and an instrument, which cut the urethra from the inside, was employed to divide the stricture. Two months after this operation, his difficulty of making water was as great as before. Since that time he has applied to various surgeons for relief, and has had a succession of bougies of different sizes passed before his admission in this hospital. At present he is suffering from a large prolapsus of the rectum, for which an operation has been performed. He makes water in a very fine stream, and, while straining to pass it, he has excruciating pain from the descent of the gut.

The first observation that is suggested by the reading of this case, short as it is, is one which I shall make in passing, for I must recur to it. It is very natural to suppose, that when you have obtained a full stream of urine, by whatever means, the patient is cured. No; he is very far from being cured. This is the peculiarity of stricture, that you must pass your instrument again and again, at regular intervals, preserving the passage open until all disposition to contraction has ceased. Whether you operate with a bougie—whether you force the stricture with a catheter, or apply caustic, or in whatever manner you destroy a stricture, so as to make the canal wide and the stream free, you have not cured your patient: neglect him from that time, and in two months he will come back to you with the same degree of stricture as before.

This is a circumstance which has deceived many: they have said, this stricture is a muscular and spasmodic contraction; we have the proof of it in the *disposition* to its return. But you must study this question properly, and first ask yourselves, what is the *disposition?* The error arises from using a word without attaching to it the proper meaning. The fact is, that the disposition to the return of the disease is the same with that which produced it, and that was inflammation; and until you find on passing your bougie that your patient does not suffer, and that the tenderness has subsided, the inflammation is not gone, or, as some authors would express it, the disposition remains, and the disease will certainly return.

There are other circumstances in this case which demand attention—the *prolapsus ani.* What is that? and how is it produced? Prolapsus ani results from the relaxation of the sphincter, and the irritation and the action of the gut within. It proceeds, then, from the disordered action of these two, or rather, I may say, these three muscles—the levator, the sphincter, and the muscular coat of the intestines. Nature intends, that whenever a portion of the gut is in action, the portion below should be relaxed. Whenever, therefore, there is irritation in the rectum, you find that there is action in the rectum, and relaxation in the anus, and the relaxation remains as long as the irritation within continues. Thus the inside of the gut comes to be turned out, and finally pushed more and more down until there is prolapsus. Now what produces it in this case? That is the point we must attend to. It is the frequent call to make water, attended with straining—the strain that accompanies stricture produces piles, or a descent of the anus, and it is very necessary that you should recollect this, because when the straining consequent upon stricture produces disease of the anus, or say disorder, not to give it a more formidable name, this increases the severity of the original symptoms. As a stricture in the urethra sometimes produces piles, so do piles and prolapsus produce pains, which to the patient's sensation are in the bladder and penis. You know very well that an operation on the anus for tying or cutting an hæmorrhoidal tumor, by disturbing the action of the muscles at the neck of the bladder, causes a necessity for the introduction of the catheter. That circumstance marks the established relation between the muscular apparatus of the anus and the muscular apparatus at the neck of the bladder. Observe, again, that irritation at the lower part of the colon, still more in the rectum itself, will produce continual *nisus* to pass urine, and the patient will complain of pain in the urethra, and be alarmed with the idea of having a stone in the bladder; while all that you have to do is, to soothe the irritated condition of the mucous membrane of the canal, and to prevent the lodgment of scybelæ. Mark, then, I beg of you, the sympathy betwixt the rectum and the bladder; the frequent call to make urine, caused by irritation in the anus; and not only the frequent desire to pass water, but pain in the bladder and in the penis; all those symptoms that give rise to the notion that there is a stone in the bladder. I have repeatedly found this fancy taking possession of the minds of medical persons. They have come to me, stating that they had all the symptoms of stone; that they had no rest from the frequency with which they made

water; that they had pain at the end of the penis; and they were afraid that I must pass a sound, and ascertain the condition of the bladder; instead of which, I have directed them to pay attention to the rectum, to use the tepid clyster, and gently to promote the action of the great intestines, and by so doing they have removed the irritation.

[The fifth case, that of B. Rowbottom, who now attends as an out patient, was next read. It was short, and stated that fistula in perineo had formed, not in consequence of stricture in the urethra, but of gonorrhœa, a fact which the lecturer said was very essential to a right understanding of this class of diseases.]

Gonorrhœa, young men think a mighty simple matter, yet it is the source of all the mischiefs of which we are now speaking. When gonorrhœa takes place in a young man of feeble and scrofulous constitution, there is another and a worse effect than either swelled testicle or even stricture, to be apprehended. Sometimes, I say, in a debilitated and strumous constitution, direct ulceration takes place without stricture, which ulceration makes a passage for the urine. In such a case you will find that you can pass the catheter freely into the bladder; that there is no stricture, but yet there is a great hole in the side of the penis, either behind or anterior to the scrotum. This is one of the most teasing cases that a surgeon has to deal with.

There is another effect of gonorrhœa which also should be borne in mind. This kind of inflammation, like any other accidental inflammation, is nothing in a good constitution, but I am speaking more particularly of patients who have a bad constitution. The inflammation from gonorrhœa will sometimes creep backwards, by what John Hunter called *continuous sympathy*: it will cease, perhaps, to have the specific character of gonorrhœal inflammation, but it will creep back to the neck of the bladder, and will there cause inflammation: inflammation in the prostate, abscess within the prostate, and abscess around the neck of the bladder, the consequence of which is, that the urine gets into these abscesses, and keeps up a continual discharge, keeps up also a continual irritation, so that the patient has rest neither night nor day, and, in fact, is teazed to death. What with the fever, the restlessness and disturbed nights, together with the copious discharge, it produces hectic, and destroys him. Now this is not generally understood, nor thought of by young men.

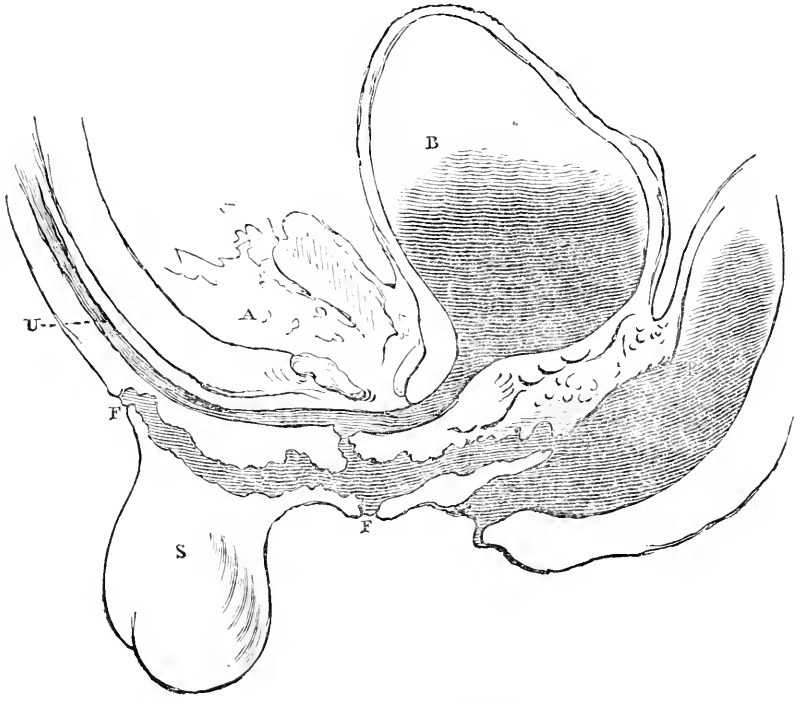
But in the consideration of this case I must beg more particularly to direct your attention to the ulceration of the urethra without stricture—an opening which it is exceedingly difficult to close. I remember that some years ago a young gentleman, a very fine spirited youth, was under my care, and his family were teazing him to marry, but this secret was on his mind—an ulceration had taken place anterior to the scrotum, and all that should have passed along the urethra escaped there. He went abroad; joined the army on the continent, and wished to throw away his life. But in every breach in which he exposed his life, and on every attack that was desperate he succeeded, was lauded, and promoted; and thus he was placed in a condition that made his escape from the importunities of his friends more difficult. You see by what secret motives a man may become a hero. But to the point: an eminent surgeon, to whom I have already had occasion to allude, (and whom I do not mention now only lest it should lead to the surmise of our patient's name,) by the application of nitric acid to the edges of the hole, drew them together, and succeeded in perfectly closing the passage. What a deal of misery was here removed!

And now let me tell you how this method by burning occurred to me: it was some years back, while my respected friend Mr. Cartwright was surgeon here. We were each of us plagued with a case: one to close a hole in the urethra, and the other to keep a hole open in the trachea: the last having a continual disposition to close, and the other shewing no disposition whatever to do so, with all the applications that I could think of. But at the same time there were in the house several cases of burns where the cicatrization, you know, takes place with such a disposition to contraction of the part that it is impossible to resist it. If a child be burned in the neck the head is all drawn down, and the parts consolidated; if there is a burn on the sides, the arm is apt to be drawn towards it; and I thought that if I could excite that disposition in the integuments around the opening, I would succeed in closing it. With this view, I took a red hot iron, about the size of this bougie, and put it on the margin of the hole, always with the point converging to the centre of the hole, and in that manner I at last succeeded in producing the *disposition* I wished. The cicatrix drew the parts together, and brought the hole from a very considerable opening to the merest pin hole, and that at last closed. That is the only method that I can suggest to you as likely to be effectual in closing an opening in the urethra when it has been made in the way here described, and is not a consequence of stricture, as I am about to explain, but a direct effect of ulceration.

[The following is a private case which I have introduced to you, but that does not signify. The gentleman who reads the case has had some trouble with the patient, and the patient now in the ward offers an exact parallel.]

CASE VI.—*Fistula in Ano, with Flatus coming through the Penis.*

J. K.—This gentleman had for many years been subject to piles. He contracted gonorrhœa, and, about the fifth week, he was seized with severe pain, deeply seated in the perineum, where an extensive abscess at length formed. The matter which was discharged was in large quantity, and it came from two openings, one in front of the scrotum, and the other behind it. It was found that the probe could be inserted from the posterior opening backwards into the rectum, and also into the urethra near the bulb. The probe also passed from the opening behind parallel to the urethra, so as to come out before the scrotum.



A—Pubes.
B—Bladder.
R—Rectum.
U—Urethra.
F F—Fistulous openings.
S—Scrotum.

All that I have to say on that narrative gentlemen, is, that it is another of those most complex and most tiresome cases that are proceeding, not from stricture, but from gonorrhœa, and occurring in an unfavourable constitution. You see, then, that this patient was in a most unhappy condition; he had an opening anterior to the scrotum; he had a large fistulous opening posterior to the scrotum; he had an opening by the side of the anus, the flatus came by the urethra; the fæces and the urine came by the opening in the perineum, and the urine fell back into the rectum. This is a sad complication.

When I passed my catheter into the bladder, there was no let or hindrance at all to its passage. That was unfortunate; because, if there had been a stricture, we should then have said, applying the great aphorism of the profession, *remove the cause* – the stricture is the cause—and, when the cause is removed, all the symptoms will be immediately alleviated. But there was here no stricture to remove. The next thing, then, was to pass a probe deep into this fistula, and then to introduce my finger into the rectum. It was with much difficulty that I made the probe pass into the rectum, so as to touch my finger; for it was at a depth of *two inches*.

The first thing to be thought of in this

case was to remedy the connexion between the rectum and the bladder, by which the contents of the rectum got into the urethra; and at the same time to attend to the free evacuation of the rectum, that the matter might not be constrained to pass into the urethra; in short, the operation of fistula in ano must be first performed. We could not venture to do this with a knife. I could not cut up all the sinuses; I could not cut upon the rectum, for the perforation is situated two inches deep, and the man would die of hæmorrhage. I am, therefore, constrained to adopt the old method of operating—to pass a leaden probe into the fistula, anterior to the anus, and so along into the rectum, and bring it out by the anus, to twist it, and gradually, by twisting from day to day, to cut down the septum between the rectum and this sinus. When you have carried the case so far that all the internal and deep parts are divided by ulceration on the wire or ligature, you may shorten the process by dividing the external part with the knife. Still in such a case you have a bad fistula in perineo to deal with, because you have an ulceration in the urethra, and the urine still passes into the sinus. Your only mode then is to correct the constitution, to free the parts from all irritation, and to prevent the fæces and urine lodging. The case I have been alluding to is greatly remedied; there is no disturbance of the anus; the parts are cicatrised, the rectum retains its contents, and it is simply a case of fistula in perineo; but with this peculiarity, that there is no stricture, nothing to remove in that way, and there is a difficulty, as I have just now stated, of closing the fistulous opening between the membranous part of the urethra and the perineum; but I think we are now succeeding in that respect. He retains his fæces, he retains his urine, and only a little moisture is observed when he makes water. This has not occurred in a patient in the house; but still the case is so similar to one that you know, that I think you may almost say you have conviction of its truth.

Case VII.—*Mortification of the Scrotum from Stricture and Extravasation of Urine, complicated with Fistula in Ano.*

P. Macarty, aged 49. This man was brought to the hospital Oct 23d. When examined in the waiting-room, the scrotum was found distended to an enormous size; it was of a bright red colour, except in one part near the perineum, where there was a black sphacelated patch. While he was crossing the hall on his way to the ward, the mortified portion of the scrotum burst. The surgeon, upon finding him in bed, made an extensive and deep incision in the lowest part of the tumor, and urine spurted out to a great distance. This was discovered to be mixed also with feculent matter; so that, in laying open the swelling, there was not only a communication with the urethra, but likewise with the rectum, disclosed.

This man was remembered by some of the pupils, as having been a patient in the hospital four years before. He was then labouring under fistula in ano, and underwent the operation for its cure, and was dismissed in six weeks. After leaving the hospital the same complaint recurred. But besides this source of distress, he has for seven years been subject to stricture of the urethra. This he confesses he did not inform his surgeon of when he was formerly in the hospital. It was so narrow, that the surgeon whom he has lately attended was fully three weeks before he could get any instrument inserted into it. A short time before he was seized with this last attack, he passed his urine in a very small stream and with great difficulty, and he had frequent calls to make it. He then perceived a swelling forming behind the scrotum, which grew gradually larger, until it suddenly assumed the dimensions which it presented when he was admitted.

For some weeks he remained in a very weak condition. The urine passed freely through the wound, and also partly through the natural passage. The sloughs gradually separated and presented a clean surface in the wound. Now he is able to get up, and he has gained flesh and a freshness in his countenance.

That is the man we have just been looking at up stairs. This is a case you see of extravasation of urine from stricture. The stricture formed in the urethra is necessarily attended with inflammation; and for this reason—that the push of urine is made behind the stricture, and the continual effort to force on the urine distends the canal behind the stricture. This at length produces ulceration of the membrane at that part. If the ulceration should go on slowly, and if inflammation should precede the ulceration, so as to consolidate the cellular membrane, you have only an abscess, and lastly a fistula; but if the ulceration should go on more rapidly, and if it should not be preceded by inflammation which causes a consolidation of the surrounding parts, and if the stricture be so narrow that the man is straining hard to pass the urine, it bursts out through the weakened membrane. He has a sensation of passing the urine because it flows from the bladder; but, unfortunately, it passes into the cellular membrane of the scrotum, instead of flowing through the penis. If the urine burst through that part of the urethra just behind the bulb, it gets access to the

cellular membrane behind the fascia of the perineum, and the fascia of the perineum directs it forward; so that the urine, instead of going backwards and shewing itself by a tumor in the perineum, shews itself in the loose cellular texture of the scrotum and penis, and those parts assume a most extraordinary and alarming appearance. You will find that after the urine has entered it the loose cellular texture is deprived of life. The cellular texture possesses very little life—its life is easily destroyed by the presence of acrid urine; so that if a man in this condition be neglected, he will come into the waiting-room precisely as this man did—like a creature half dead, having an older appearance than what should belong to his years, faint, sick, and pale; and when you disclose the part, there is a dark redness of the scrotum and penis, with a great patch of blackness at the lower part of it. As soon as I saw this patient his case was obvious, and I desired him to be carried directly to bed. I went to relieve him, but you are told that so far was he gone that the mortified part burst as they were carrying him along the passage. However, I put in a sharp-pointed bistoury, in such a way as to open the back part of the scrotum freely. Why not open it freely?—it is dead—mortified. But you should also use the instrument in such a way that the point goes under the fascia of the perineum, which answers two purposes: first, it lets out the extravasated urine, and, secondly, it prevents any more from collecting, by making the passage for the urine free. That is the object of this operation, and therefore do not take a lancet and puncture here and there on the enlarged scrotum. Recollect that besides getting out the fluid, you are to prevent more entering the scrotum, and you are to make a free passage for the urine from that part where it has burst from the urethra. The patient has suffered long with pain and difficulty in making water, with fever, before it has come to this, and when at last the urine is extravasated, and mortification has taken place (and mortification in a part will soon shew its influence on the constitution), the man is miserably low. It is your duty now, having made a free passage for the urine, to soothe the parts by warm anodyne fomentations and opiates, to support him by wine and proper diet, thus taking care that the powers of nature do not sink too low; for if they do, then he is seized with vomiting, and you lose him.

Now, gentlemen, it is in this condition that the surgeon, who is very, very fond of operating, must suspend his hand; for in this state the patient is reduced so low by suffering and by fever, and ultimately by mortification, that if you lay him on the table and attempt any protracted or painful operation, you will find that the powers of life will give way altogether. The first thing you have to do is to see that he revive a little, in short, that he exhibits such an appearance as this old man does, having a face twice the breadth that he had when he came into the house, with such powers as belong to a man of his age. His condition will then allow you to do that which is necessary in order to perfect a cure, or at least to afford him further relief.

The next case to be read is that of a narrow stricture where there is as yet no abscess in the perineum, and no fear of a bursting of the urethra.

CASE VIII.—*Impermeable Stricture, with Retention of Urine.*

Richard Peck, æt. 45, was admitted July 11th, suffering from retention of urine. He was relieved by the warm-bath, castor-oil, and opium. He is found to have a stricture situated near the bulb, which is so extremely narrow that it is with the greatest difficulty the finest bougie can be passed into it. Notwithstanding the narrowness of his stricture, he evacuates his bladder without much distress. A bougie is daily inserted into the stricture, and is allowed to remain for twenty minutes.

This is a case requiring me to be particular in describing to you how it is to be managed, in order that all those complex mischiefs which you see to be the consequence of a mismanaged stricture do not occur in any patient of yours. I must, therefore, ask you to give me your attention next week, when I will enter fully into the subject.

MEM.—The last case was one of a patient who had an injury of the perineum from being thrown on the pummel of the saddle—abscess and fistula in perineo.

LONDON HOSPITAL.

Encysted Tumor of the Labium Pudendi—Immediate Operation, in consequence of obstinate Constipation, inducing a slight suspicion of its being Hernial.

MARTHA LOCKWOOD, aged 40, admitted Wednesday, October 24th, under the care of Mr. Scott, with a swelling in the left labium pudendi. She stated that it appeared suddenly, about three weeks ago, in violently straining herself. Her bowels have been constipated since Saturday last (29th). On the Monday following she was seen by a medical gentleman, who ordered purgative medicines for her, but which did not procure evacuations

from the bowels. She took calomel and jalap, four drops of croton oil, and several clysters were administered, but without effect. She had vomiting, hiccupping, and tenderness of the abdomen. As this gentleman suspected that it was a case of labial hernia, he sent the woman to the hospital on the 24th instant. Upon examination, there was found a tumor, about the size of a large egg, situated in the left labium: it felt like an encysted tumor, and appeared to have a narrow neck extending upwards by the side of the rectum, but received no impulse in coughing. At a consultation of the surgeons, although the swelling was not supposed to be hernial, in consequence of the somewhat suspicious character of the symptoms it was thought advisable to set aside all doubt by an operation.

The woman being placed upon the table, as in the operation for lithotomy, Mr. Scott made an incision down its centre, and then carefully detached part of its connexion to the surrounding parts; in the performance of which, in consequence of its close adhesion, a small opening was made into the vagina. As no doubt now remained of its nature, a small opening was made in the cyst, when a quantity of brown fæcal-looking matter immediately gushed out. All fears were, however, immediately set at rest by the absence of any fæcal smell. The opening was then enlarged, and a serous cyst exposed, with a small opening at the bottom, which was found to terminate in a cul de sac. The whole of the cyst was then dissected out, and at the end of it was found another small cyst, containing a soft transparent fluid. Two vessels were secured, and then some sutures were applied. The woman was sent to bed, and ordered

Cal. gr. i. e. Extract. Cathart. gr. v. omni horâ donec alvus responderit.

25th.—Her bowels have been twice freely relieved this morning; is going on favourably.

The sutures were removed the third day after the operation; the communication with the vagina was united, and the wound soon healed by granulations.

Fracture of the Pelvis, of several Ribs and their Cartilages, attended with Emphysema of the Right Clavicle and of the Left Radius and Ulna—Death after twelve weeks, from Sloughing of the Back.

—— Ceely, about 60 years of age, and spare habit of body, was admitted, under Sir W. Blizard, July 18th, having sustained some severe injuries from the passage of the wheel of a waggon across her body. On examination, there was found a comminuted fracture of the right clavicle, a spicula of bone almost protruding through the skin; a fracture of both bones of the left fore arm, considerable emphysema, and a crepitus was felt midway between the anterior superior spine of the ilium and the spine of the pubis. There was also inability to move the left thigh. The woman was in a state of great depression, and was not expected to survive many hours. In the evening, as she was unable to evacuate her bladder, a catheter was introduced, and a small quantity of urine drawn off.

19th.—She has rallied a little, and was free from pain.

Ordered cold lotion to the injured parts.

She never experienced any difficulty in breathing, and in a few days was able to pass her water. She continued gradually to mend till about six weeks after the accident, when a slough formed on the lower part of the back, from which there was a very copious discharge; this sore extended until the greater part of the sacrum was exposed. Every thing was done to support her strength and to protect from pressure the affected part of the back, but without avail, for she gradually sunk, and died October 2d, twelve weeks after the accident.

Sectio Cadaveris.—The bones of the forearm and the clavicle were united; there was discovered to have been fractures of the four upper ribs, also the cartilages of two ribs on the right side; and of the three upper and fifth and sixth ribs on the left, all united. Adhesions existed between the surfaces of the pleura on both sides of the chest. Lungs and viscera of the abdomen healthy. There was a fracture extending through the obturator foramen completely united.

Medullary Sarcomatous Tumor in the Pelvis.

William Avant, aged 20, and apparently much out of health, was admitted September 27th. Since April last he has experienced pain in the hip and down the thigh, and been troubled with a frequent desire to pass his urine, which was attended with pain. Some time back he applied as an out-patient at Guy's Hospital, where a catheter was attempted to be passed into his bladder, but without success. Latterly he was under the care of a medical gentleman in the Commercial Road, who sent him to this hospital. He complains now of difficulty in passing his water, and of great pain in the region of the bladder. His urine is healthy; there is a swelling extending from the right groin into the perinæum and inner part of the right nates juxta anum. As the case was at first suspected to be an abscess connected with disease of the urethra, the symptoms of which did not appear urgent, he

was ordered the warm-bath, and leeches daily to the tumor. On the following day a catheter was introduced, and passed with the utmost facility apparently into the bladder; still nothing passed but blood, mixed with a soft gelatinous substance, which had no urinous smell. The fore-finger of the left hand being introduced into the rectum, the catheter could be distinctly felt apparently in the urethra; its point was gently elevated, but it would not pass into the bladder. A considerable tumor, however, could be felt by the finger.

Contin. Hirud. perinæo et Balu. tepid. Tinct. Opii, xxx. o. n. Mist. Camph. c. Ammon. Carbon. ter die.

October 5th. — Upon examination, a sense of fluctuation being perceived at the inner part of the nates, an incision was made, from which escaped a large quantity of a bloody gelatinous matter, and the fore-finger was passed its whole length into a mass of a similar substance. A catheter was again introduced, but with the same result as on the previous day.

Ordered a poultice to the part, and Tr. Opii ɱxl. statim.

In the evening he had passed about half a pint of urine, and was nearly free from pain, but complained of great weakness.

6th, 9 A.M.—Feels great distress from being unable to pass his water. Abdomen tense; pulse quick, small, and weak. A catheter was again attempted to be passed, but failed.

Ordered fomentations to the abdomen.

1 P.M.—The catheter was again tried, but without success. Abdomen more tense, but not tender. He takes scarcely any nourishment.

9 P.M.—Complains of considerable distress from inability to pass his water. There was some appearance of hypogastric tumor, but by no means evident. As his sufferings were supposed to arise from urine being retained in the bladder, an incision was made in the course of the linea alba, immediately above the pubes, and a long curved trocar passed in the direction of the bladder, when the stilette was withdrawn. As no urine flowed, it was passed to its full length, but no water escaped: the trocar was therefore withdrawn, when a quantity of the same gelatinous substance escaped from the pubes.

Ordered Tr. Opii ɱlx.

He died the following morning, at four o'clock, rather suddenly; and, shortly afterwards, his abdomen was observed to be enormously distended.

Sectio Cadaveris, 33 hours after death.—The body had undergone the most rapid putrefaction; not a feature of his face was distinguishable; the scrotum and penis were greatly distended. A quantity of gas escaped from the abdomen when opened. No appearance of peritonitis. The bladder contained a little urine, and was pushed over to the left side by a quantity of medullary matter occupying the greater part of the right side of the pelvis, involving various structures, and appearing to grow from the horizontal ramus of the pubes, the greater part of which bone was soft and implicated in the disease, which had just made its way into the acetabulum. The trocar had passed into the disease on the right side of the bladder. The vesicle end of the urethra was completely destroyed, so that there was no continuous canal to the bladder. The rectum was not pressed upon.

By Dr. Elliotson.

DISEASES OF THE HEAD AND NERVOUS SYSTEM.

HYDROCEPHALUS ACUTUS.

Morbid Appearances.—After death, gentlemen, from the disease of which I was speaking in the last lecture—hydrocephalus, you may find the same marks of inflammation and congestion in the brain itself and its membranes which I mentioned when speaking of phrenitis. Sometimes you will find nothing more than that, so that the strabismus or squinting, the dilatation of the pupils, and the coma, are not necessarily the result of effusion: you may find no effusion whatever, notwithstanding the child has died from this disease, and although previous to death there was strabismus, dilated pupils, and unconsciousness. Death will arise from the mere irritation and excitement which the child has undergone, and the compression and perhaps fulness of the vessels; but certainly it is not necessary that there should be compression from effused fluid. Frequently you will find the same congested and inflammatory state on the scalp that there is within, and a great deal of serum, just as I mentioned has been occasionally observed in common phrenitis.

But sometimes you will not find any of these things: you will sometimes find nothing. I have myself opened children who have died of this disease and found nothing; the congestion and the signs of an inflammatory state having subsided, I presume, after death, and the blood having left those vessels in which it ought not to have existed, and returned to its usual route. It is possible for even the marks of inflammation to cease after death before you examine the body.

If, however, there be fluid, it varies very much as to its clearness: as I mentioned, when speaking of phrenitis, it is sometimes perfectly limpid and uncoagulable. It will be found of course in the brain or upon the brain, and it is generally found to amount to from two to six ounces. The brain at large is sometimes found œdematous after this affection, especially at the corpus callosum, the fornix, and the septum lucidum, and this œdematous state exists either alone or in conjunction with ventricular effusion. In infants there is great ventricular effusion at the same time that you find œdema of the brain, and not unfrequently the same circumstance is noticed in adults; but it is generally seen in infants. The brain, after this disease, is very often found soft in particular parts; particular parts appear to have become softened by the inflammation; and it is not an uncommon thing to meet with scrofulous tubercles in the brain itself or its membranes, shewing the pre-disposition to disease in the brain. These of course existed before the hydrocephalus was set up; but they shew the tendency to disease of the brain.

The longer the disease has lasted, the greater in general is the turgescence of the vessels, and the softer is the brain, according at least to Dr. Gölis, who has had more experience, I suppose, of this disease than any one else. He also mentions that effusion will sometimes take place in a very few hours. Now and then we have marks of inflammation in the liver and in the intestines: it is not by any means uncommon for an inflammatory state of these parts to co-exist with this affection.
